# Preface

Analytical science impacts on all aspects of life in the twenty-first century. Reliable, high-quality analytical data are essential prerequisites for monitoring health (and disease), for enhancing the efficiency of industrial processes, improving product quality and reducing emissions, and for studying complex biogeochemical interactions in the environment. New analytical techniques and methods are key drivers for advances in drug discovery, forensic science, and life sciences, for monitoring the quality of foodstuffs, pharmaceuticals, and other consumer products, for furthering our understanding of environmental processes, and for monitoring compliance with legislation.

The means by which analyses are achieved varies from simple color tests for the qualitative identification of anions and cations through to complex and expensive computer-controlled instrumentation for quantitative determination of trace amounts of a single organic compound or element in a complex matrix. Increasingly, such instrumentation is a hybrid of techniques for separation and detection that requires extensive data processing. So wide has the subject of Analytical Science become that complete coverage, providing information that is comprehensible to an interested scientist, can only be achieved in a multi-volume encyclopedia such as this. Even then, the length of each of the approximately 550 articles needs to be limited in order to keep the size of the encyclopedia manageable.

The encyclopedia covers all facets of modern analytical science, with articles from an international authorship of experts in their specialist fields. The articles cover three broad areas: analytical techniques (e.g., mass spectrometry, liquid chromatography, atomic spectrometry); areas of application (e.g., forensic, environmental, clinical); and analytes (e.g., arsenic, nucleic acids, polycyclic aromatic hydrocarbons). The authors and Editorial Advisory Board members are drawn from all continents and we are grateful to the great majority who met their deadlines.

The boundaries of Analytical Sciences are constantly pushing into new areas and we have taken a broad view of what material should be included. Comprehensive indexing and cross-referencing are important features that should allow rapid access to relevant information for users of the encyclopedia.

The first edition of this encyclopedia, published in 1995, was the inspiration of Robert Macrae. Following the success of the Encyclopedia of Food Science, Food Technology and Nutrition, of which he was a leading editor, he realized how valuable a similar Encyclopedia of Analytical Science would be. Dr. Macrae served as managing editor of the first edition until his unexpected death in November 1993. Without him this encyclopedia would never even have begun.

# Introduction

It is increasingly appreciated that knowledge of the nature and composition of materials gives a greater control of their properties. As the range of materials becomes more diverse and valuable, analytical science, which determines this nature and composition, also achieves greater recognition and attention.

Many attempts have been made to provide a satisfactory definition of analytical science. The most recent is that proposed by the Working Party on Analytical Chemistry of the Federation of European Chemical Societies (*Analytical Chemistry* (1994) 66; 98A–101A); it reads:

Analytical chemistry is a scientific discipline that develops and applies methods, instruments, and strategies to obtain information on the composition and nature of matter in space and time.

Thus, analytical science includes within its remit not only a considerable amount of chemistry, but also an increasing proportion of biochemistry, physics and electronics, computer science, mathematics and chemometrics, and even management and economics. But these are combined into a distinct area of science with its own philosophy, procedures, and objectives.

The increasing scope and the impressive rate of change of analytical science over the 10 years that have elapsed since the publication of the first edition of this encyclopedia are reflected in the extensive changes that have been made to the contents in producing this second edition. The majority of the articles are new or have been extensively rewritten, and all topics have been selected on the basis of their relevance to analytical science at the beginning of the twenty-first century. New articles include DNA sequencing, endocrine disrupting chemicals, ‘lab-on-a-chip’ technologies, field flow fractionation, nitric oxide, prions, and solid-phase microextraction, again giving a flavor of the breadth and relevance of modern analytical science. In a similar vein, subjects now considered to be less appropriate have not been included in this second edition.

The large number of articles in this encyclopedia and the wide variety of the subject matter emphasize the considerable scope of modern analytical science. The articles fall mainly into three classes:

- Analysis for particular analytes
- Analysis of particular types of samples
- Analytical techniques

Particular analytes that are the subjects of articles in the encyclopedia include a wide range of classes of organic compounds (e.g., amino acids, dioxins, humic and fulvic compounds, lipids, nucleic acids, polycyclic aromatic hydrocarbons, proteins) as well as specific compounds (e.g., ethanol, glucose). There is also an extensive selection of compounds having particular types of function (e.g., antioxidants, neurotoxins, pesticides, vitamins). Inorganic elements are not assigned individual articles, except for those elements where their speciation provides significant analytical challenges (e.g., arsenic, carbon, chromium, selenium, sulfur). The concentrations at which such analytes can be determined range from per cent levels, through trace concentrations ( $\mu\text{g ml}^{-1}$ ) to ultratrace levels ( $\text{ng ml}^{-1}$ ,  $\text{pg ml}^{-1}$ , and even less). Such is the sensitivity of some modern analytical techniques and procedures that the detection of individual molecules is now possible in some instances.

The types of sample that must be analyzed are numerous. They include raw materials, intermediates, products, and effluents of industrial processes. Analysis is essential for controlling the manufacturing process, the quality of the product, and the hazards of any discharges into the environment. Articles are included, therefore, on such diverse products as adhesives, building materials, ceramics, glasses, and paints, as well as on process analysis per se. There is a section on food analysis and on pharmaceutical compounds. Other groups of materials that are the subject of many articles are clinical samples and forensic specimens. Specific materials that merit individual articles include blood, coal, fertilizers, and meat. Particular importance is placed on the means of obtaining representative samples, and the processes to which they may be subjected before the analytical measurement is made. Equally, the quality of the analytical process is a matter that is dealt with in some depth, including standards, traceability, accreditation, and interlaboratory studies.

A considerable proportion of the encyclopedia is dedicated to descriptions of techniques and to the wide range of applications for which they are used. These include the instrumentation available for making the analytical measurement, for example, atomic absorption and emission spectrometry, chromatography and

electrophoresis, fluorimetry, mass spectrometry, nuclear magnetic resonance spectroscopy, X-ray fluorescence spectrometry, and the various surface analysis techniques. Other techniques of great utility are described, such as immunoassays, amplification reactions (including the polymerase chain reaction), and radiochemical methods.

With such a diversity of topics, some overlap between articles is inevitable and, indeed, desirable. Each article is intended to be self-contained, but extensive cross-references are included to enable further information on particular topics to be found elsewhere in the encyclopedia. Even in articles where there might, at first sight, scope for duplication, it will be seen that each article has its own distinct perspective. For example, there are articles on ethanol, on forensic sciences, determination of alcohol in body fluids, and on food and nutritional analysis, alcoholic beverages, but it can readily be seen that the emphasis in each article is very different.

A glance at the table of contents, in volume 10, will show that some topics merit a large number of articles, a reflection of their importance in current analytical science. Several techniques, for example, mass spectrometry, nuclear magnetic resonance spectroscopy, atomic emission spectrometry, microscopy, the various chromatographic techniques (e.g., gas, liquid and thin-layer), and electrophoresis, merit a series of articles, as do areas such as food and nutritional analysis, forensic sciences, archaeometry, pharmaceutical analysis, sensors, and surface analysis. Each of these collections of articles, written by experts in their fields, provides at least as much up-to-date information on that particular subject as a complete textbook.

In conclusion, this encyclopedia provides detailed information by acknowledged experts on most aspects of modern analytical science. It is designed to be easy to access and, if further information is required, bibliographies are provided. The grouping of subjects and the cross-referencing should emphasize both the variety and the unity of analytical science; that there is a thread that links what at first sight are very diverse topics, but which in fact demand a common philosophy. This ‘analytical approach’ is what the encyclopedia is all about.

**Paul Worsfold, Alan Townshend and Colin Poole**

## **Dedication**

The original idea for the *Encyclopedia of Analytical Science* came from Dr. Robert Macrae, who played a large part in its realization of the first edition, and scientific editor, until his sudden, untimely death in November 1993. This work is dedicated to him; we hope that it will serve as a lasting memorial to his enthusiasm for publishing, and commitment to scientific endeavor.

## **Disclaimer**

This encyclopedia is a guide providing general information concerning its subject matter; it is not a procedural manual. The readers should consult current procedural manuals for state-of-the-art instructions and applicable government safety regulations. The publisher and the authors do not accept responsibility for any misuse of this encyclopedia, including its use as a procedural manual or as a source of specific instructions.

### Introduction

Neutron activation analysis is a powerful nondestructive multielement technique that can be applied to the determination of over 60 elements in a broad range of matrices. The method involves activation of the sample in a source of neutrons followed by  $\gamma$ -ray spectrometry to identify and quantify the induced

activity, and there from the concentration of the element in the sample. Although access to a reactor is required for the irradiation, the samples may then be transferred to another laboratory for analysis, in contrast to prompt activation where analysis is carried out while the sample is being irradiated. The advantages of the technique over other multielement methods for trace elements are that: (1) solids can be analyzed without any sample dissolution, and consequently the method is particularly useful for the analysis of insoluble materials like plastics, carbon fiber, and boron compounds, and in the determination of volatile elements that may be lost on dissolution, such as arsenic, selenium, and mercury; (2) extremely low detection limits may be attained, for example, the detection limit for gold in a 10 g sample of silicon is 6 pg per g; and (3) the method is

nondestructive and therefore the sample may be re-analyzed by the same, or an alternative, method.

## Basic Theory

The method is based on the fact that most elements have one or more stable isotopes that can be made radioactive on interaction with a neutron. For example, reactions that can occur with aluminum are

The  $(n, \gamma)$  interaction normally occurs in a thermal neutron flux, while the  $(n, p)$  and  $(n, \alpha)$  reactions are induced with fast neutrons. Many of these products are radioactive and decay with the production of  $\beta$  and  $\gamma$  radiation. **Figure 1** is the decay scheme for  $^{198}\text{Au}$ , showing the main  $\gamma$ -ray energy at 0.4118 MeV.  $\gamma$ -Rays are readily identified by their characteristic energies and so the activity of the product radionuclide is measured using  $\gamma$ -ray spectrometry in multielement neutron activation analysis. **Figure 2** shows schematically how the induced activity of the sample changes as it is irradiated for a time,  $t_i$ , and counted for a time,  $t_{\text{meas}}$ , after a decay period,  $t_d$ . The  $\gamma$ -ray intensity of the radionuclide,  $A_p$ , measured over time,  $t_{\text{meas}}$ , is quantified from the accumulated spectrum and expressed as counts per second (cps).

**Figure 1** The decay scheme for  $^{198}\text{Au}$ . (Based on data from Browne E and Firestone RB (1986) *Table of Radioactive Isotopes*. New York: Wiley; and Hammed MA, Lowles IM, and MacMahon TD (1992) Decay scheme data for  $^{154}\text{Eu}$ ,  $^{198}\text{Au}$  and  $^{239}\text{Np}$ . *Nuclear Instrumentation and Methods in Physics Research A* 312: 308–316.)

This count rate can be corrected for decay since irradiation ceased ( $\exp(-\lambda t_d)$ ), detector efficiency ( $E$ ), and branching ratio ( $P$ ), which is the number of  $\gamma$ -rays emitted per disintegration of the nucleus, in order to calculate the activity of the radionuclide,  $A_{t_i}$

$$A_{t_i} = A_p \exp(-\lambda t_d) / EP \quad [1]$$

where  $\lambda$  is the decay constant ( $= \ln 2 / T_{1/2}$ , where  $T_{1/2}$  is the half-life) of the product radionuclide and  $t_d$  is as shown in **Figure 2**.

The probability of an interaction taking place, called the cross-section, is highest for  $(n, \gamma)$  reactions and so these activation products are generally most useful. The activation rate or activity generated ( $A$ ) of the generated radionuclide is dependent on the cross-section for the reaction ( $\sigma$ ), the number of target nuclei ( $N$ ), and the neutron flux ( $\phi$ ):

$$A = \sigma N \phi \quad [2]$$

The number of target nuclei is dependent on the amount of element X in the sample and the abundance of the target isotope. If we take 1 g of element X, we have  $N_A / A_w$  atoms, where  $N_A$  is Avogadro's number, and  $A_w$  is the relative atomic mass of element X. If the isotopic abundance of the target is  $\theta$ , and the amount of the element X in grams is  $w$ , the number of target nuclei  $N$  is given by

$$N = N_A \theta w / A_w \quad [3]$$

Substituting [3] into [2]

$$A = \sigma N_A \theta \phi w / A_w \quad [4]$$

The net rate of production of the radionuclide ( $dN^*/dt$ ) is dependent on the activation rate

**Figure 2** Activity,  $A$ , as a function of time during irradiation and decay. The integrated activity measured is indicated by the shaded area.

(Eqn [2]) and the decay rate of the product ( $\lambda N^*$ ):

$$dN^*/dt = \sigma N\phi - \lambda N^* \quad [5]$$

where  $N^*$  is the number of radioactive nuclei. Therefore,

$$N^* = \sigma\phi N(1 - \exp(-\lambda t))/\lambda \quad [6]$$

So the disintegration rate, or activity, after irradiation for time  $t_i$  ( $A_{t_i}$ ) is given by

$$A_{t_i} = \sigma N_A \theta \phi w (1 - \exp(-\lambda t_i))/A_w \quad [7]$$

Equation [7] is the activation equation.

Substituting the activation equation [7] into eqn [1] gives

$$A_p = \frac{\sigma N_A \theta \phi EP w (1 - \exp(-\lambda t_i))}{A_w \exp(-\lambda t_d)} \quad [8]$$

The radionuclide will continue to decay during the measuring time ( $t_{\text{meas}}$ ), as shown in **Figure 2**, so it is necessary to correct  $A_p$  by the factor  $\lambda t_{\text{meas}}/(1 - \exp(-\lambda t_{\text{meas}}))$ , unless  $t_{\text{meas}}$  is short compared to the half-life of the radionuclide (and therefore to  $t_d$ ).

The amount of element X in the sample can be deduced from

$$w = \frac{A_p A_w \exp(-\lambda t_d)}{\sigma N_A \theta \phi EP (1 - \exp(-\lambda t_i))} \quad [9]$$

This expression is readily simplified when standards of known composition are irradiated and counted with the samples. If the irradiation and decay conditions are kept constant and all measurements are made with a constant neutron flux and detector geometry, the concentration by weight of element X becomes the simple ratio:

$$\frac{w_{(\text{standard})}}{w_{(\text{sample})}} = \frac{A_{p(\text{standard})}}{A_{p(\text{sample})}}$$

where  $w_{(\text{standard})}$  and  $w_{(\text{sample})}$  are the amounts of element X in the standard and the sample, respectively, and  $A_{p(\text{standard})}$  and  $A_{p(\text{sample})}$  are the measured count rates in the standard and sample, respectively.

In most analytical problems this is the most simple and straightforward procedure.

## Instrumentation

### Irradiation Devices

There are a number of different neutron sources available, including the 14 MeV neutron generator

and the smaller  $^{252}\text{Cf}$  or Am/Be sources, but the source most commonly used for activation analysis is the nuclear reactor. The reactors are based on a core of uranium enriched in  $^{235}\text{U}$ . The uranium core is surrounded with moderator of water or graphite to slow the neutrons emitted on fission. The heat generated during fission is dissipated with a coolant such as water. The rate of production of neutrons is controlled by rods made of neutron-absorbing material such as cadmium. Facilities for neutron activation range from low-power research reactors of 100–300 kW, to the larger reactors generating megawatts of power. The thermal neutron fluxes available in these sources range from  $10^{15}$  to  $10^{18} \text{ m}^{-2} \text{ s}^{-1}$ . Neutron fluxes of  $10^{15}$  to  $10^{16} \text{ m}^{-2} \text{ s}^{-1}$ , available in the lower-power research reactors, provide adequate sensitivity for most applications and these research reactors often provide better access and irradiation devices more suited to the activation of samples for analysis. The American TRIGA and Canadian Slowpoke reactors are typical pool-type facilities with light-water cooling and moderation. Most of the neutrons in the pool-type reactor are thermalized and have the most suitable energy for the  $(n, \gamma)$  reactions used in activation analysis. They also have a significant epithermal neutron component that may be used in the absence of thermal neutrons by employing a cadmium filter to remove neutrons with energies below 0.5 eV. The Slowpoke reactor in particular was designed as a low-power device suitable for operation in a university. The design, in **Figure 3**, shows the compact core, the central control rod, and the irradiation tubes.

Each reactor has its own design of irradiation facilities, but where activation analysis is carried out routinely it would be expected that there would be both manually loaded irradiation tubes for long irradiations, and pneumatic systems for irradiations of a few minutes. In addition there may be irradiation tubes with thermal neutron filters for epithermal neutron activation and a cyclic activation system for repeated activation of the same sample. The layout of the irradiation devices in the Imperial College (UK) research reactor is shown in **Figure 4**. The degree of automation can be quite variable and in some facilities hundreds of samples are irradiated totally automatically, in others even short irradiations with a pneumatic system may be timed manually. The most important consideration in activation analysis is that the timings on irradiation are reproducible. It will not matter if the length of irradiation cannot be measured very accurately provided it is repeatable and both standard and sample have the same length of irradiation.

**Figure 4** A schematic diagram of the Imperial College reactor showing the pneumatic and manual irradiation facilities.

### Detection by $\gamma$ -Ray Spectrometry

High-resolution semiconductor germanium detectors, operated at liquid nitrogen temperature, are used for  $\gamma$ -ray spectrometry when neutron activation analysis is used to determine a number of elements. Photoelectric absorption in the germanium crystal, leading to ionization, is used to detect and measure the energy of the  $\gamma$ -ray in the detector. The electric charge created by the ionization is collected by applying several thousand volts across the crystal through the preamplifier. The preamplifier amplifies the small pulse from the detector ( $\sim 0.05 \text{ pC MeV}^{-1}$ ) with a gain of  $\sim 2 \text{ V pC}^{-1}$  to  $\sim 0.1 \text{ V MeV}^{-1}$ . These pulses are shaped and amplified to a maximum of  $\sim 10 \text{ V}$ , depending on the gain setting. The analog-to-digital converter (ADC) changes the amplified pulse into a digital signal that is deposited as a count in the appropriate channel number in the analyzer. The analysis equipment required has been simplified by modern electronics, and the power supply and high voltage for the detector, the amplifier, the ADC, and the analyzer are now combined. This single unit, plus the detector and a personal computer is all the equipment required for analyzing the samples.

Several different types of  $\gamma$ -ray detectors are used for activation analysis. The most generally useful one is about a 40-ml volume crystal of n-type or p-type germanium, which covers a range of energies from 50 keV to several MeV. The resolution of the detectors is important and for adequate resolution of overlapping peaks it is usually necessary to use a detector that gives a full-width at half-maximum of 1.8–2.0 keV for the  $^{60}\text{Co}$  peak at 1.33 MeV. A thin beryllium window in the casing facilitates the measurement of low-energy  $\gamma$ -rays and X-rays down to a few keV. A planar germanium crystal is used to optimize

the resolution of low-energy  $\gamma$ -rays but the efficiency is poor at higher energies, as demonstrated by the plot of detector efficiency in Figure 5. Compton scattering occurs when a  $\gamma$ -ray interacts with the detector material and transfers some energy by inelastic scattering to the recoil electron, resulting in lower-energy background in the spectrum. A detector with a high peak-to-Compton ratio will give best signal-to-background ratio and hence detection limits.

Figure 6 shows a typical  $\gamma$ -ray spectrum, in this case for an air particulate sample on filter paper, Spectra, which are often complex, are processed to locate, identify, and evaluate the peaks using a personal computer or workstation running software purchased from the manufacturer of the electronics or with programs written in-house. Peak-search programs work through the spectrum, loading those channels where the counts are above the background using a preset value for sensitivity. The spectrometry system is calibrated prior to use using standard sources with precisely known energies and the peak locations are calculated from the centroid channel number using the energy calibration.

The  $\gamma$ -ray spectral lines are identified and assigned to the appropriate radionuclide using a library of known  $\gamma$ -ray energies. Interferences from radionuclides emitting a  $\gamma$ -ray of similar energy can lead to peaks being wrongly identified. The library of radionuclides can be comprehensive and the relative intensities for lines from a particular radionuclide can be used as a further check on its identity, provided that the efficiency of the detector is known. The same radionuclide can be produced by competing nuclear reactions from different elements and so it is also important to check the source of the radioactivity. The experienced analyst uses standards and reference materials to check for sources of these interferences.

**Figure 5** The efficiency curves for a coaxial p-type, a coaxial n-type, and a planar germanium detector. (Reprinted with permission from Parry SJ (1991) Activation spectrometry in chemical analysis.)

**Figure 6** The  $\gamma$ -ray spectrum of air particulate on filter paper, irradiated for 35 h, and counted for 6 h, 25 days after irradiation.

## Methodology

### Quantitative Analysis

The total number of counts under the peak is measured for each  $\gamma$ -ray energy, by subtracting the estimated counts in the background from the total peak area. The background under the peak is estimated by averaging the counts in the channels on either side of the peak. Multiplets are separated using Gaussian fitting routines to estimate the contributions from each peak. The activity in counts per second is compared to a known standard irradiated and counted under the same conditions to determine the concentration of the element in the sample.

### Use of Standards

Standards are prepared as solids or in solution from pure elements or compounds. Standard solutions sold for inductively coupled plasma (ICP) spectrometric techniques are ideal. These are prepared as multi-element standards for use as liquids or dried on a suitable solid substrate. The standard should have a similar geometry to that of the sample. The composition is not so critical, however, and standards can be used over several orders of magnitude. If irradiation and counting conditions are kept constant during analysis, the standard data may be stored in a database for use on future occasions, with inclusion of a monitor to check the irradiation and counting conditions. In variable conditions of irradiation, decay and  $\gamma$ -ray spectrometry standards are included with the samples during analysis, and this is the common

approach. Reference materials of suitable composition are used to check the validity of the whole procedure.

### Irradiation

The simplicity of sample preparation is one of the main advantages of the technique. Solids, liquids, and even gases are analyzed directly as received with no prior treatment. The sample is sealed in a suitable container, usually of polyethylene or quartz glass, and placed in the irradiation position in the reactor. When quantitative analysis is carried out with chemical standards, it is necessary to ensure that the samples have a constant geometry for irradiation and  $\gamma$ -ray spectrometry. Samples are therefore used in powder form or as chunks of uniform shape and thickness. In the case of liquids, identical volumes must be used to provide consistent geometry and great care is required to ensure that no leaks occur in the irradiation site. Reactor operators have strict control over samples allowed in the irradiation devices and hazardous materials will not be permitted.

Once encapsulated, the samples are usually placed in an outer irradiation can of polyethylene or aluminum. The irradiation can is then placed for the required time in the irradiation site. When irradiation is complete the sample is taken out of the reactor, either manually or through a pneumatic system. At this stage the samples may be sent directly to a counting device as part of a totally automated system on site, or to an analyst who could be working on the other side of the world (Figure 7).

**Figure 8** A carousel-type sample changer for large samples, designed for a standard lead castle. (Reprinted with permission from EG & G Instruments, Wokingham; L.E. Pink Engineering Ltd, Reading and Fab Cast Engineering Ltd, Dartford.)

### Counting

Detector systems have a variety of configurations and the endcap of the detector casing may be vertical, horizontal, or even at an angle. The sample is positioned in a sample holder, which is usually made of plastic to avoid attenuation of the  $\gamma$ -rays. The efficiency of the detector is dependent on the distance between the radioactive source and the detector endcap, so the sample holder is designed to give reproducible geometry, at a fixed distance. Sample changers are used for automated counting and they can be purchased commercially or manufactured in house. The designs vary from carousel-like devices, shown in Figure 8, which move the samples over a vertical dipstick detector on a circular turntable, to pneumatic systems that blow the samples sequentially through a tube to the counting position, usually with a detector in a horizontal configuration.

### Choice of Irradiation and Counting Conditions

The choice of the analytical procedure is dependent on the elements to be determined and the sample

matrix. Neutron activation analysis is a multielement method of analysis that is usually applied to the determination of more than one element. However, because of the minimal sample preparation required, it is also sometimes useful for just one element in the analysis of difficult materials. If there is one particular element to be determined, the conditions can be optimized for that element. The choice of irradiation time will depend on the half-life of the radionuclide of interest, but as a general rule an irradiation of one to two half-lives will be sufficient. In the case of radionuclides such as  $^{60}\text{Co}$ , which has a half-life of over 5 years, it is not possible to irradiate for so long. The decay period before analyzing the samples will depend on many unavoidable factors, including accessibility and transportation, but ideally they should be counted before the radionuclide of interest has decayed significantly. The sample is counted for sufficient time to allow good statistics on the peak of interest, and there is little point in counting after the radionuclide has gone through two half-lives.

Normally the sample is analyzed for more than one radionuclide, so the choice of irradiation, decay, and counting times is a compromise. However, there are a small number of procedures that are typically used for the determination of the whole suite of elements, and these are shown in Table 1 for a variety of sample types. In general, sodium, magnesium, aluminum, silicon, sulfur, chlorine, potassium, titanium, vanadium, manganese, copper, iodine, and dysprosium are measured after a short irradiation of between 10 s and 10 min and a thermal neutron flux of between  $5 \times 10^{15}$  and  $5 \times 10^{17} \text{ m}^{-2} \text{ s}^{-1}$ . Decay periods of 10 s to 2.5 h are allowed, before counting for 20–1000 s. The remaining elements are determined with a long irradiation for 1–72 h, with decay periods of 20 h to 30 days, and counting times of 2000 s to 12 h.

### Sources of Error

The major interferences in the  $\gamma$ -ray spectrum result from high backgrounds due to elements in the sample matrix. Detection limits are restricted by the background continuum of energy produced from other  $\gamma$ -emitters due to the Compton effect. For example, sodium in blood, scandium in rocks, and manganese in steel will all activate well and cause background activities, thus giving poorer detection limits for other elements. This background effect is limited by using specialized equipment such as a Compton suppression detector or by activation with epithermal neutrons to reduce the thermal neutron activation of the matrix.

**Table 1** Typical conditions for multielement neutron activation analysis

Type of sample	Neutron flux ( $m^{-2}s^{-1}$ )	Irradiation time	Decay period	Count time	Elements determined
Hair <sup>a</sup>	$5 \times 10^{15}$	30 s	10 s	20 s	Ag, Cl, F, Se

Interferences that can lead to erroneous results include overlapping peaks from radionuclides with similar  $\gamma$ -ray energies and the production of the same radionuclide from two different isotopes as the result of different nuclear reactions, for example, the production of  $^{28}\text{Al}$  from the  $^{27}\text{Al}(n, \gamma)$  reaction and the  $^{28}\text{Si}(n, p)$  reaction. There is also the possibility of neutron self-shielding, where the activation of the isotope is diminished by the absorption of neutrons within the matrix of the sample; in the case of very high concentrations of the element, self-shielding by the element of interest itself may occur.

Based on counting statistics, the  $3\sigma$  detection limit is given by  $3B^{0.5}$ , where  $B$  is the background area. The error associated with a net signal area  $A$  on a background  $B$  is  $(A + 2B)^{0.5}$ , and the error for the sample is combined with the error for the standard to give total counting error. In addition, errors associated with counting geometry and neutron

flux variation on irradiation have to be taken into account.

### Safety

In common with all techniques involving radioactivity, particular care is taken to ensure that the hazard from the irradiated samples is minimized. The electronics of the  $\gamma$ -ray spectrometry systems used in this technique cannot work at very high count rates and so it is not usually necessary or even advisable to induce high levels of radioactivity in samples for activation analysis. There is now a greater stress on the principle of keeping risk as low as possible, and so use is made of automation to reduce the contact time for radiation workers. **Figure 9** shows a totally automated system for the irradiation and analysis of samples, avoiding any exposure to radiation for the operator.

## Applications

Activation analysis can be applied to most types of material, including food products, urine, feces, air pollution particulates, river water, marine samples, vegetation, soils, sediments, ores, plastics, petroleum products, pharmaceuticals, coal, metals, alloys, semiconductor materials, clays, ceramics, and glasses. Variations in the analytical procedures for multielemental analysis are dictated by the matrix and so are detection limits. Table 2 compares the detection limits for an air particulate sample on filter paper and those for a deep-sea sediment to the detection limits in the ideal situation. Petroleum products, pharmaceuticals, plastics, carbon products, and air filters are not activated to produce  $\gamma$ -rays, so the spectrum is free of any interferences from the matrix. This means that detection limits are low and over 60 elements can be determined simultaneously. Soils, sediments, clays, and glasses have elements such as sodium and scandium in their matrices that can produce background activities that result in poorer detection limits for most elements.

Metals generally activate well, which means that they are not easily analyzed for trace elements. However, metals such as vanadium and titanium can be left after irradiation to allow the short-lived activity to decay before counting the longer-lived

radionuclides of interest. Semiconductor materials such as pure silicon are ideal for analysis once the activity from the matrix has decayed, and this is a growing area of application. The fact that neutron activation analysis does not require sample dissolution is of particular value in all the applications that have been mentioned here.

## Charged Particle Activation

## Introduction

Activation analysis (AA) is an analytical method for determining the (stable isotope) concentration of trace elements in the bulk of a sample. Speciation (i.e., discrimination between different oxidation states of the analyte element or between different compounds) is not possible with AA. AA is based on nuclear reactions leading to radionuclides specific for a given element. After irradiation these radionuclides are measured. Identification of the radiation emitted by measuring its energy and/or half-life provides qualitative analysis, while measuring the number of particles or photons emitted per second (i.e., (radio) activity) yields quantitative analysis. Charged particle activation analysis (CPAA) is based on charged

particle-induced reactions, while neutron activation analysis (NAA) and photon activation analysis (PAA) make use of neutron- and photon-induced reactions, respectively. Although CPAA, NAA, and PAA are all based on the same principle of AA, charged particle-induced reactions (and consequently CPAA) are fundamentally different from neutron- or photon-induced reactions.

## Stopping Power and Range

When a sample is irradiated with charged particles, only a small fraction of them induce nuclear reactions. Charged particles passing through matter lose energy mainly by interaction with electrons, leading to excitation or ionization of the target atoms or molecules (at least for the energy interval of interest for CPAA).

The stopping power of a target for a charged particle is defined as the energy loss per unit of thickness

and is commonly expressed in CPAA in terms of  $\text{MeV g}^{-1} \text{cm}^2$ :

$$S = -\frac{1}{\rho} \frac{dE}{dl} \quad [1]$$

where  $E$  is the energy (MeV),  $\rho$  is the mass density ( $\text{g cm}^{-3}$ ), and  $l$  is the thickness (cm).

For a sufficiently high energy ( $> 1$  MeV) the stopping power of the elements can be calculated by the Bethe formula. The stopping power depends on the charged particle and its energy and the target material. The stopping power is roughly proportional to  $Z_a^2 m_a / E_a$ , where  $Z_a$  is the atomic number,  $m_a$  is the

mass, and  $E_a$  is the energy of the charged particle. The stopping power increases with decreasing atomic number ( $Z_a$ ) of the target material. Tables 1 and 2 summarize some stopping power data, which can be calculated using the SRIM (stopping and ranges of ions in matter) program of Ziegler.

For mixtures and compounds the stopping power can be calculated from stopping power data for the elemental components by the additivity rule of Bragg and Kleeman:

$$S = \sum w_i \cdot S_i \quad [2]$$

**Table 1** Stopping power in ( $\text{MeV g}^{-1} \text{cm}^{-2}$ ) of 10 elements for proton energies ( $E_p$ ) between 1 and 20 MeV and deuteron energies ( $E_d$ ) between 2 and 40 MeV

where  $w_i$  is the mass fraction of component  $i$ , and  $S_i$  is the stopping power of component  $i$ .

A charged particle loses only a very small fraction of its energy in a single interaction with an electron. As it is barely deflected from its original direction, charged particle paths are straight lines. Charged particles with the same incident energy will be stopped at a given depth in the target, the range. The relation between the range ( $R$ ) of a charged particle with incident energy  $E_i$  in a particular target and the stopping power ( $S$ ) of that target for that particular charged particle is given by

$$R = \int_{E_i}^0 \left( \frac{1}{\rho} \frac{dE}{dL} \right)^{-1} dE = \int_0^{E_i} \left( \frac{1}{S} \right) dE \quad [3]$$

The range is commonly expressed in CPAA as mass thickness ( $\text{g cm}^{-2}$ ). Ranges of protons or deuterons are larger than ranges of helium-3 or helium-4 particles and ranges in the very low atomic number targets (e.g., hydrogen) are smaller than for high atomic number targets.

## Nuclear Reactions

CPAA is based on a nuclear reaction  $A(a,b)B$  where a stable target nuclide (at rest)  $A$  is irradiated by accelerated charged particles  $a$  to form a radionuclide  $B$  with emission of one (or several or a cluster of) particle(s)  $b$ . Important characteristics are the minimum particle energy required to induce a nuclear reaction and the probability that this reaction will take place. As a charged particle is slowed down when traversing matter, this probability (cross-section, see below) should be known as a function of the energy.

A nuclear reaction  $A + a \rightarrow B + b + Q$  or  $A(a,b)B$  that releases energy is called an exoergic reaction:  $Q > 0$ . A nuclear reaction where energy must be provided (as kinetic energy of the charged particle) is called an endoergic reaction:  $Q < 0$ . In an exoergic (endoergic) reaction, mass-energy is thus lost (created). Considering the equivalence between mass and energy,

$$E = mc^2 \quad [4]$$

where  $E$  is energy in joules,  $m$  is mass in kilograms, and  $c$  is the velocity of light ( $2.997\,92 \times 10^8 \text{ m s}^{-1}$ ), the  $Q$ -value in joules is given by

$$Q = (m_A + m_a - m_B - m_b)c^2 \quad [5]$$

where  $m_i$  are the masses of the nuclides  $A$ ,  $a$ ,  $B$ , and  $b$  in kilograms.

More practically, the  $Q$ -value in MeV is given by

$$Q = 931.5(m_A + m_a - m_B - m_b) \quad [6]$$

where  $m_i$  are the masses of the nuclides  $A$ ,  $a$ ,  $B$ , and  $b$  in unified atomic mass units (u) because, according to eqn [4],  $m = 1 \text{ u}$  corresponds to  $E = 931.5 \text{ MeV}$ . Mass in unified atomic mass units  $1 \text{ u} \approx 1.66054 \times 10^{-27} \text{ kg}$ . Energy in electronvolts:  $1 \text{ eV} \approx 1.602 \times 10^{-19} \text{ J}$ .  $Q$ -values (in MeV) have been compiled by Nuclear Data Centers.

Endoergic reactions ( $Q < 0$ ) are only energetically possible for charged particles with a minimum kinetic energy, the threshold energy  $E_t$ . The threshold energy is slightly higher than  $-Q$ . The compound nuclide, formed by collision of the charged particle  $a$  and the target nuclide  $A$ , retains a fraction of the kinetic energy of the charged particle as kinetic energy. This fraction is approximately

$$\frac{A_a}{A_A + A_a} \quad [7]$$

where  $A_i$  are the nucleon numbers of the nuclides  $A$  and  $a$ , and is thus 'lost' to compensate the shortage of mass-energy for an endoergic reaction. Nucleon (or mass) number  $A = Z + N$ , where  $Z$  is the proton (or atomic) number and  $N$  is the neutron number. Thus, for endoergic reactions ( $Q < 0$ ) the threshold energy is given by

$$E_t \approx \frac{-Q(A_A + A_a)}{A_A} \quad [8]$$

For exoergic reactions ( $Q > 0$ ) the threshold energy is zero by definition.

The Coulomb barrier also determines the minimum energy of the charged particle needed to induce a nuclear reaction. The Coulomb repulsive force between the target nucleus and the charged particle dominates at 'large' distances and increases with decreasing distance of separation between charged particle and target nucleus, until the charged particle comes within the range of the attractive nuclear forces of the target nucleus. At some particular distance (i.e., the sum of the charged particle and target nucleus radii) the forces balance each other, and at shorter distances the attractive nuclear force dominates. The decrease in kinetic energy is given by the Coulomb barrier

$$E_C(\text{MeV}) = 1.02 \frac{A_A + A_a}{A_A} \frac{Z_A Z_a}{\sqrt[3]{A_A} + \sqrt[3]{A_a}} \quad [9]$$

The kinetic energy that the charged particle has lost through the Coulomb barrier is released again when a nuclear reaction occurs. Consequently, the Coulomb barrier does not influence the energetics

of a nuclear reaction except that a charged particle must have a kinetic energy higher than the Coulomb barrier in order that the reaction can occur. Table 3 gives approximate values of the Coulomb barrier for protons, deuterons, helium-3, and helium-4 particles as a function of the atomic number of the target. Quantum mechanical treatment of the problem indicated that the reaction probability for particles with kinetic energies lower than the Coulomb barrier is not exactly zero but is very low and drops rapidly as the energy of the charged particle decreases.

The probability of a nuclear reaction occurring is expressed as the (nuclear reaction) cross-section; it has the dimensions of area. This originates from the simple picture that the probability for a reaction between the target nucleus and the incident charged particles is proportional to the geometric cross-section that the target nucleus presents to a beam of charged particles. The geometric cross-section is of the order of magnitude of  $10^{-28} \text{ m}^2$ . The barn ( $1 \text{ b} = 10^{-28} \text{ m}^2$ ) is used as a unit for reaction probability. The cross-section for a particular reaction (also called partial reaction cross-section) depends on the energy of the charged particle. It is zero for charged particles below the threshold energy of that reaction and very low below the Coulomb barrier. At higher energies the cross-section increases up to a maximum (typically 1 b) and decreases as more complex reactions become competitive. Experimental or calculated cross-section data (i.e., excitation functions) have been compiled by Nuclear Data Centers.

## Interferences

For the determination of an analyte element A, based on the reaction  $A(a,b)B$  where B is a radionuclide, three different types of interferences can be distinguished: nuclear, spectral, and matrix interference.

If the radionuclide B is formed out of another element C than the analyte element A, the determination of A by reaction  $A(a,b)B$  can be subject to nuclear interference from C by the reaction  $C(c,d)B$ . Generally, particles a and c are identical. However, nuclear interference by secondary particles (e.g., fast or thermalized neutrons produced by  $(x,n)$  reactions where x is the charged particle) should also be considered. Only if the threshold energy of the interfering reaction is higher than the threshold energy of the analyte reaction, can nuclear interference be avoided by a proper choice of the charged particle energy. To obtain high sensitivity the charged particle energy is chosen just below the threshold energy of the interfering reaction.

If a radionuclide D is formed out of another element C than the analyte element A, the determination of A by reaction  $A(a,b)B$  can be subject to spectral interference from C by the reaction  $C(c,d)D$ . Three methods can be applied to avoid spectral interference:

1. Proper choice of the charged particle energy (see Nuclear Interference).
2. Selective measurement of radionuclide B besides radionuclide D by spectrometry or decay

curve analysis. The former is possible if the energies of the  $\gamma$ -lines are more different than the energy resolution of the  $\gamma$ -spectrometer used (typically 2 keV for an HPGe detector). The latter is possible if the half-lives of the radionuclides C and D are different. For considerably different half-lives, a sufficiently short (long) decay time makes it possible to measure the short- (long-) lived radionuclide selectively.

3. Chemical separation of B from D. This is only possible if B and D are not radioisotopes of the same element.

A special case is spectral interference from the matrix. CPAA being primarily a method for trace element determinations, the concentration of the analyte element is much lower (typically  $10^6$  times) than the concentration of the major matrix element(s). If a major matrix element (C) is activated, it often happens that the activity of D is much higher (also  $10^6$  times) than that of B. Even for quite different  $\gamma$ -energies or half-lives, selective measurement becomes quite difficult. The interference can only be avoided by a proper choice of the incident energy or by chemical separation of B from D. In the former case an instrumental analysis (i.e., without chemical separation) is possible.

## Standardization

‘Standardization’ matches the concept of ‘calibration’ generally used in analytical chemistry. The number of radionuclides produced per unit time by irradiation of an infinitesimally thin target is determined by the balance of the increase due to nuclear reactions and the decrease due to radioactive decay:

$$\frac{dN}{dt} = I \cdot \sigma \cdot n \cdot dl - \lambda \cdot N \quad [10]$$

where  $N$  is the number of radionuclides for the nuclear reaction considered,  $t$  is the time (s),  $I$  is the number of charged particles per unit time, or beam intensity ( $s^{-1}$ ),  $\sigma$  is the (partial) nuclear reaction cross-section for the nuclear reaction considered ( $cm^2$ ),  $n$  is the number of target nuclides for the nuclear reaction considered per unit volume ( $cm^{-3}$ ),  $l$  is the thickness of the target (cm), and  $\lambda$  is the decay constant of the radionuclide formed for the nuclear reaction considered ( $s^{-1}$ ).

The number of radionuclides formed after an irradiation time  $t_i$  is found by integration of eqn [10]. On condition that the beam intensity  $I$  is constant during irradiation, the activity is then

$$A = \lambda \cdot N = I \cdot \sigma \cdot n \cdot dl \cdot (1 - \exp(-\lambda t_i)) \quad [11]$$

For a ‘thick’ target, i.e., thicker than the range  $R$  of the charged particles used, the activity is obtained by integration of eqn [11] between 0 and  $R$ . It can be demonstrated that the beam intensity  $I$  is nearly constant as a function of the depth  $l$ . On condition that the analyte element is homogeneously distributed in the sample, one obtains

$$A = I \cdot n \cdot \rho^{-1} \cdot (1 - \exp(-\lambda t_i)) \int_0^R (\sigma \cdot \rho) dl \quad [12]$$

Using the stopping power  $S$  (eqn [1]) the integral in eqn [12] can be expressed as a function of the energy,

$$\int_0^R (\sigma \cdot \rho) dl = \int_{E_t}^{E_i} \left( \frac{\sigma}{S} \right) dE \quad [13]$$

where  $E_i$  is the incident energy and the integration limit  $E = 0$  (corresponding to  $l = R$ ) may be replaced by the threshold energy  $E_t$ , as the cross-section is zero for an energy below the threshold energy of the nuclear reaction.

Although, in principle, the concentration of the analyte element can be calculated by eqns [12] and [13], in CPAA a relative method is usually applied whereby a standard (s) and a sample (x) are irradiated separately but with the same incident energy  $E_i$ . From eqns [12] and [13], the concentration of the analyte element in the sample is then

$$c_x = c_s \cdot \frac{A_x \cdot I_s \cdot [1 - \exp(-\lambda \cdot t_{i_s})]}{A_s \cdot I_x \cdot [1 - \exp(-\lambda \cdot t_{i_x})]} \cdot F \quad [14]$$

$$F = \int_{E_t}^{E_i} \left( \frac{\sigma}{S_s} \right) dE / \int_{E_t}^{E_i} \left( \frac{\sigma}{S_x} \right) dE \quad [15]$$

The number of target nuclides per unit volume ( $n$ ) can be replaced by the concentration of the analyte element ( $c$ , e.g., in mg per kg), at least if the isotopic abundance of the target nuclide is equal for sample and standard (which is mostly the case).

The concentration (‘concentration’  $c$  matches the SI quantity mass fraction  $w$ ) of the analyte element in the sample ( $c_x$ ) can thus be calculated by eqn [14] from the concentration of the analyte element in the standard,  $c_s$ ; the ratio of the activity in sample and standard at the end of irradiation,  $A_x/A_s$ ; the ratio of the beam intensity for standard and sample,  $I_s/I_x$ ; the irradiation time,  $t_i$ ; the decay constant,  $\lambda = \ln 2/t_{1/2}$  where  $t_{1/2}$  is the half-life; and the  $F$ -factor (eqn [15]) representing the correction for the difference in stopping power of sample and standard.

The  $F$ -factor can be calculated according to eqn [15] if (1) the stopping power of sample ( $S_x$ ) and standard ( $S_s$ ) and (2) the nuclear reaction cross-section ( $\sigma$ ) are known, both as a function of energy in the energy interval between the threshold energy ( $E_t$ )

and the incident energy ( $E_i$ ). The first condition can be fulfilled in a large number of cases. If the major element concentration of the sample is known and if the matrix does not change during irradiation, the stopping power of the sample can be calculated. It is obvious that the stopping power of the standard can be calculated. If the second condition is also fulfilled, the most obvious method for calculation of the  $F$ -factor is numerical integration of eqn [15].

As the second condition is not always fulfilled, two approximative standardization methods have been proposed that do not require knowledge of the nuclear reaction cross-section. The first approximative method makes use of stopping power data for sample and standard,

$$F \approx S_x(E_M)/S_s(E_M) \quad [16]$$

at an energy  $E_M$ , i.e., the average of incident and threshold energy,

$$E_M = (E_i + E_t)/2 \quad [17]$$

The second approximative method makes use of range data for sample and standard at both the incident and threshold energies:

$$F \approx \frac{R_s(E_i) - R_s(E_t)}{R_x(E_i) - R_x(E_t)} \quad [18]$$

These two approximative methods are equivalent and yield accurate results if one or more of the following conditions are fulfilled: (1) the atomic number of (the elemental components of) sample and standard are comparable; (2) the threshold energy of the nuclear reaction used is high; or (3) the incident energy is high as compared with the threshold energy.

The average stopping power method requires knowledge of the cross-section and is in principle also an approximative method, but with a negligible systematic error compared with the previous two methods. The  $F$ -factor is calculated using stopping power data for sample and standard,

$$F \approx S_x(E_m)/S_s(E_m) \quad [19]$$

at an 'average energy'  $E_m$  calculated as

$$E_m = \int_0^{E_i} (E \cdot \sigma) dE / \int_0^{E_i} \sigma \cdot dE \quad [20]$$

Up to now, all methods have required knowledge of the stopping power of the sample, which can be calculated for all elements and for any mixture or compound with known composition. Many samples, however, have a very complex matrix composition that is not always accurately known. Irradiation with

charged particles can cause substantial heating in materials of low thermal conductivity, e.g., silicates, such as environmental and geological materials. This can give rise to evaporation of, for example, the organic fraction present in the sample. The introduction of systematic positive errors in quantitative analysis is to be feared from enrichment of the analyte element during irradiation and the fact that the stopping power calculated for the sample is too high. Indeed, the stopping power of a material, taking into account the organic fraction also, is higher than the stopping power of the inorganic fraction of that material (the stopping power of hydrogen for protons is about three times higher than the stopping power of, for example, silicon dioxide). If the organic fraction (or part of it) evaporates during irradiation, a too high stopping power is used in the calculations and consequently a too high concentration is obtained.

Consequently, an internal standard method has been proposed for materials with unknown or variable matrix composition. The idea is that by using the known concentration of one element (i.e., the internal standard) and by measuring the induced activity of the internal standard, a correction can be calculated for all elements to be determined (i.e., the analyte elements) without knowledge of the matrix composition of the sample. Approximative methods not requiring knowledge of the reaction cross-section have also been proposed.

The 'two reactions' method is derived from the average stopping power method and also makes use of an internal standard of known concentration. The main advantage is that no stopping power data at all are necessary, so that the accuracy of the analytical method is not influenced by the accuracy of the stopping power data.

So far, a relative method has been applied, whereby a standard and a sample are irradiated separately but with the same incident energy. In the standard addition method, however, a sample is irradiated, and separately the same sample to which an accurately known amount of the analyte element is added. As both matrices are almost identical (only trace amounts of analyte are added), the  $F$ -factor is unity and consequently the method does not make use of any stopping power data.

## Experimental

### Irradiation

For CPAA charged particles have to be accelerated up to an energy higher than the Coulomb barrier (to obtain high reaction cross-section and thus detection limit) and lower than the threshold energy of

reactions more complex than  $(x,n)$  or  $(x,\alpha)$  reactions, where  $x$  is the charged particle (to avoid nuclear interferences). Energies between a few MeV and 20 MeV should be available for protons and deuterons and up to 30 MeV for helium-3 or helium-4 particles. Accelerators that cover this energy range of interest for CPAA are the isochronous cyclotron, the 'tandem Van de Graaf' accelerator or the linear accelerator (linac). An isochronous cyclotron with variable energy is generally used.

Irradiation with a charged particle beam can cause substantial heating of the sample. Therefore, efficient cooling of the target is the major concern in target design. The simplest target design is possible for solid samples with good thermal conductivity, not powdered and available as a foil or sheet with a thickness slightly larger than the range. Irradiation under vacuum is then possible with the sample mounted on a water-cooled sample holder. For powdered samples or samples with poor thermal conductivity, irradiation in a helium atmosphere has been developed. Applications of CPAA for the analysis of liquids are less obvious, as many optical (AAS, OES) or mass spectrometric (ICP-MS) methods of analysis exist for diluted aqueous solutions.

When a relative method is used in CPAA, the ratio of the beam intensity for standard and sample has to be determined experimentally. As knowledge of the absolute beam intensity is not required, it is common practice to cover sample and standard with a thin (much less than the range) I-monitor foil. The induced activity in the I-monitor foil is then a measure of the beam intensity. Pure metal foils are the obvious choice: they are good thermal conductors, monoelemental, and available in different thicknesses.

To avoid recoil nuclides from the I-monitor foil in the sample (or the standard) a recoil foil is inserted between the I-monitor foil and the sample (or the standard). As the range of the recoil nuclides is much lower than the range of the charged particles commonly used in CPAA, a few micrometers of aluminum foil is sufficient to stop the recoil nuclides completely, while the energy of the charged particles is reduced by a minor (but not negligible) fraction.

### **Chemical Etch**

Although charged particles have a limited range in matter, CPAA is considered as an analytical method for determination of the concentration in the bulk of a sample rather than at the surface. Accordingly, interference from the analyte element at the surface has to be avoided. This is possible for solid samples that are not powdered simply by etching the sample before irradiation, at least if further contamination of

the surface can be avoided until the end of irradiation (contamination after irradiation gives no interference). For the determination of light elements (boron, carbon, nitrogen, and oxygen) at low concentrations, however, the latter condition cannot always be fulfilled. This is the case, for example, for the determination of bulk oxygen concentration in aluminum. A freshly etched aluminum sample is exposed to air again and has an aluminum oxide layer that will also be activated. Chemical etch after irradiation is then the appropriate method. A few micrometers of the activated surface will be removed.

### **Radiochemical Separation**

Instrumental analysis is possible if spectral interference can be avoided by a proper choice of the incident energy or the measuring conditions (see Interferences). If not, the radionuclide B, formed from the analyte element A, has to be separated radiochemically from interfering radionuclide(s) D, formed out of interfering element(s) C. The latter case is called radiochemical analysis, in contrast to instrumental analysis for the former. This section deals with some major differences between radiochemical separation and common chemical separation, used for non-nuclear methods of analysis.

For most charged particle-induced reactions the atomic number of the radionuclide B is different from that of the analyte element A. This is the case for  $(p,n)$ ,  $(p,\alpha)$ ,  $(d,n)$ ,  $(d,\alpha)$ ,  $(^3\text{He},n)$ ,  $(^3\text{He},d)$ ,  $(\alpha,n)$ , and  $(\alpha,d)$  reactions, but not for  $(p,d)$  and  $(^3\text{He},\alpha)$  reactions. The radiochemical separation to be developed for CPAA is thus different from that for all non-nuclear analytical methods and for some other methods based on activation analysis, such as thermal- and fast-NAA (using the  $(n,\gamma)$  and  $(n,2n)$  reactions, respectively) and PAA (using the  $(\gamma,n)$  reaction). Also, in principle, it is not necessary to separate the matrix, but rather the radionuclide(s) formed out of the matrix element(s). Again, the atomic number of the radionuclide(s) is usually different from that of the matrix element(s). Owing to the chemical separation involved, CPAA is considered to be an independent analytical method, not subject to the same systematic errors as other analytical methods.

A radiochemical separation has three important advantages compared with a common chemical separation: (1) Inactive carriers can be added for the elements to be separated (B and D). This avoids the difficulties of a chemical separation at the trace level. (2) Reagent impurities (or blanks) do not influence the detection limit capabilities of the analytical method. (3) Separations may not be quantitative and even not reproducible (see below).

In the choice and development of a radiochemical separation the following seven points have to be considered.

1. *Selectivity of the separation.* As already pointed out (see Interferences), the induced matrix activity (D) can be up to  $10^6$  times higher than the activity to be measured (B). It is not possible to resolve such a low activity in the presence of such a high activity. In such unfavorable cases the decontamination factor (ratio of D before to after separation) should be  $\sim 10^4$  or better.
2. *Quantitativeness of the separation.* A separation that provides quantitative recovery of B is to be preferred. If the separation is not quantitative and not even reproducible, determination of the yield for each individual separation is possible. Two pathways can be followed: addition before separation of an accurately known amount of inactive (active) carrier and measurement of the mass (activity) of the carrier after separation.
3. *Speed of the separation.* To obtain an optimum detection limit, the time needed to perform the whole separation procedure should not exceed a few half-lives of the radionuclide to be measured.
4. *Use of inactive carrier.* It is not only an advantage but usually also a necessity to add an inactive carrier of the elements to be separated. Indeed, if the atomic number of the radionuclide B is different from that of the analyte element A (which is mostly the case, see above), this radionuclide B is produced 'carrier free'. The number of radionuclides (N) can be calculated from the activity (A) and the half-life ( $t_{1/2}$ ):

$$N = A \cdot t_{1/2} / \ln 2 \quad [21]$$

For  $A = 1 \text{ kBq}$  and  $t_{1/2} = 1 \text{ day}$ , the amount of substance is  $10^{-16} \text{ mol}$ . It is clear that, if there is no accidental addition of inactive element B (e.g., impurity in the matrix or reagents), it can be very difficult to separate chemically such a low mass.

5. *Detection efficiency of the measurement.* To obtain the optimum detection limit, the activity should be measured with the highest possible detection efficiency. The latter is also determined by the geometry (size and distance from the detector) of the source. Separation procedures ending with large volumes of solution are less favorable than those ending with a precipitate.
6. *Self-absorption of the source.* Self-absorption of the source to be measured is, in principle, not a problem, as long as the absorption is identical for all samples and standards. Self-absorption can be important for low-energy  $\gamma$ -rays or sources containing components of high atomic number.

7. *Health risk.* Health risk is quantified as dose expressed in the SI unit sievert ( $1 \text{ Sv} = 1 \text{ J kg}^{-1}$ ). The dose equals the amount of absorbed radiation energy per unit mass, multiplied by a weighing factor for radiation  $w_r$ , to take into account the biological effects of different radiations (for  $\gamma$ -radiation,  $w_r = 1$ ). The maximum permissible dose for occupational workers is 20 mSv per year. Natural sources provide 2–6 mSv per year. The activity level required for precise  $\gamma$ -measurements (kilobecquerels) provides no health risk for external radiation ( $\text{nSv h}^{-1}$  at 30 cm). The induced matrix activity, however, may be much higher. It is good practice first to separate the main matrix activity, choosing a procedure that limits manual intervention to the strict minimum. Ion exchange chromatography, for example, is a better choice than (manual) solvent extraction. Ingestion of radioactive material is to be avoided by appropriate laboratory practice.

The experimental development of a radiochemical separation can be supported by the use of radiotracers. The chemical separation is simulated step by step with addition of radiotracers (and inactive tracers also) for the element to be separated (B) and for the interfering element(s) (D), in order to check quantitiveness and selectivity, respectively. The tracer has to be brought to the same chemical form as the radionuclide to be separated. This is often not possible for the dissolution step preceding the actual separation procedure. Therefore, the dissolution procedure selected should guarantee quantitative recovery of the radionuclide to be measured.

There is no need to apply the radiochemical separation to the standards, at least if monoelemental standards are used (i.e., the pure analyte element or a compound of it). However, standards and samples have to be measured with identical detection efficiency. Therefore, the standards are brought into exactly the same geometrical form as the samples after separation. If the last step of a separation is ion chromatography, the standards are dissolved and the total volume is brought exactly to the volume of the eluate. Possible differences in self-absorption have to be considered (e.g., because the acid used for the elution differs from the one used to dissolve the standard).

### Measurement of Radioactivity

Charged particle-induced reactions, such as (p,n) and (p, $\alpha$ ) reactions, yield radionuclides that are too rich in protons and consequently decay by positron ( $\beta^+$ ) emission or electron capture (EC), mostly followed by gamma ( $\gamma$ ) emission. Positrons are emitted with

energy between zero and a characteristic maximum energy. Electron capture involves measurement of X-rays or Auger electrons and is of no importance for CPAA.  $\gamma$ -Rays are monoenergetic. A radionuclide (and the analyte element the radionuclide is formed from) can be identified by its characteristic  $\gamma$ -photon energy (qualitative analysis). The (radio)activity measured (i.e., the number of positrons or  $\gamma$ -photons measured per second) provides quantitative information. A limited number of radionuclides are pure positron emitters. Positron emitters are measured indirectly by the annihilation radiation: a positron loses its kinetic energy, it annihilates with an electron (i.e., both electron masses are converted into energy) and two  $\gamma$ -photons are emitted in opposite directions. The energy of both  $\gamma$ -photons is 511 keV, i.e., the rest mass of the electron. It is clear that information about the characteristic maximum energy is lost during the annihilation process. A positron emitter is then to be identified by its half-life. It is clear that  $\gamma$ -spectrometry is the method of choice, except for pure positron emitters.

## Applications

The most obvious application of CPAA is the determination of traces of light elements such as carbon, nitrogen, and oxygen in the bulk of very pure metals and semiconductors. The analytical methods routinely used are combustion in an oxygen stream and measurement of the carbon dioxide formed (for carbon), the Kjeldahl method (for nitrogen), and reducing fusion (for nitrogen and oxygen). The detection limit is of the order of mg per kg and systematic errors are to be feared because of the effects of surface contamination, reagent blanks, and non-quantitative recovery of the gases. Activation analysis is not subjected to the same kind of systematic errors. Surface contamination can be avoided by chemical etch after irradiation (see Experimental); reagent blank errors do not occur; if instrumental analysis is not possible, the yield of a radiochemical

separation can be determined, even if not reproducible (see Experimental). Because of unfavorable nuclear characteristics, thermal neutron activation cannot be applied for the determination of these light elements. Activation analysis with fast neutrons or photons has lower sensitivity (higher detection limit) than CPAA.

Nuclear data for the determination of boron, carbon, nitrogen, and oxygen by CPAA are summarized in Table 4. For short-lived radionuclides such as oxygen-14 and oxygen-15, only instrumental analysis is possible. For longer-lived radionuclides, a chemical separation can be applied if necessary. Beryllium can be separated by anion chromatography; carbon by combustion in an oxygen stream or dissolution in an oxidizing acid followed by trapping of the carbon dioxide formed; and nitrogen and fluorine by steam-distillation as ammonia and hexafluoro-silicate, respectively. Beryllium-7 and oxygen-14 are  $\gamma$ -emitters and qualitative and quantitative measurement is performed with a  $\gamma$ -spectrometer. The other listed nuclides are pure positron emitters to be identified by their half-lives. Nuclear interference cannot always be avoided. As the concentration of the interfering elements is generally lower than that of the analyte elements, this interference can usually be neglected or corrected for. As a monoelemental standard, either the pure element is used or a pure compound with well-known stoichiometry and good stability during irradiation. Correction is necessary for different stopping powers of sample and standard (see Standardization).

## CPAA for Surface Characterization

Although CPAA has been widely applied for bulk analysis, it is also applicable for surface characterization within strict limitations.

CPAA for surface characterization is based on irradiation of a 'thin' surface layer, i.e., the thickness of the surface layer ( $\sim$  nm to  $\mu$ m) is much lower than the range of the charged particles used ( $\sim$  mm). Moreover, the substrate (i.e., the layer on which the

**Table 4** Nuclear data for the determination of boron, carbon, nitrogen, and oxygen by CPAA

	Reaction	$E_t$ (MeV)	$t_{1/2}$	Radiation ( $E_\gamma$ , keV)	Nuclear interference	Standard
Boron	$^{10}\text{B}(p,\alpha)^7\text{Be}$	0	53.4 days	$\beta^+$ , $\gamma$ (478)	Li	B, $\text{H}_3\text{BO}_3$
	$^{10}\text{B}(d,\alpha n)^7\text{Be}$	1.3			Li	
	$^{10}\text{B}(d,n)^{11}\text{C}$	0	20.4 min	$\beta^+$	None	B
Carbon	$^{12}\text{C}(d,n)^{13}\text{N}$	0.3	9.97 min	$\beta^+$	None	C, polyethylene
Nitrogen	$^{14}\text{N}(p,n)^{14}\text{O}$	6.3	70.5 s	$\beta^+$ , $\gamma$ (2313)	None	$\text{NaNO}_3$ , nylon-6
	$^{14}\text{N}(p,\alpha)^{11}\text{C}$	3.1	20.4 min	$\beta^+$	B	
	$^{14}\text{N}(d,n)^{15}\text{O}$	0	2.05 min	$\beta^+$	None	
Oxygen	$^{16}\text{O}(^3\text{He},p)^{18}\text{F}$	0	109.8 min	$\beta^+$	F, Na	$\text{SiO}_2$
	$^{16}\text{O}(t,n)^{18}\text{F}$	0				None

surface layer is deposited) should not contain the analyte element(s). The goal is to determine the partial mass thickness, i.e., mass of the analyte element per surface unit, e.g. mg Ti per  $\text{cm}^2$  for a  $\text{TiO}_2$  surface layer. The induced activity is proportional to the mass thickness as it equals  $c_x \times$  the denominator in eqn [18],  $E_t$  being replaced by  $E_o$ , i.e., the outgoing energy, slightly lower than  $E_t$ .

The partial mass thickness(es) determined can be used to calculate (1) the elemental composition of a surface layer or (2) the total mass thickness knowing the stoichiometry of the surface layer. Moreover, the thickness in nm or  $\mu\text{m}$  can be calculated knowing the density of the surface layer material.

Examples are the determination of (1) the Cu/Y and Ba/Y ratios in YBCO ( $\text{YBa}_2\text{Cu}_3\text{O}_{6+\delta}$ ), which strongly influence the resistivity of this high-temperature super conductor and (2) the mass thickness of Al,  $\text{Al}_2\text{O}_3$ , or  $\text{TiO}_2$  layers on PET foil, assuming the stoichiometry mentioned, which improve the water- and airproof characteristics of this packing material.

## Analytical Capability

CPAA is an analytical method for the determination of trace elements in the bulk of a sample. CPAA can also be applied at higher concentration levels, but then other, more common analytical methods can yield even better results more conveniently. Determination of a specific compound or the oxidation state of an element (i.e., speciation) is excluded. CPAA is considered to analyze the bulk of a sample, as the activated depth (slightly less than the range) is between 0.1 and 1 mm and because surface contamination can be avoided by chemical etch after irradiation. The sample mass analyzed depends on the activated depth and the beam diameter (typically 0.5–2 cm).

No general statement can be made about the elements that can be determined and the samples that can be analyzed, because these depend on the nuclear characteristics of the target nuclide (isotopic abundance), the nuclear reaction (cross-section and related parameters such as threshold energy and Coulomb barrier), and the radionuclide induced (half-life, radiation emitted, energy, and its intensity) for the analyte element, the possible interfering elements and the major components of the sample. CPAA can solve a number of important analytical problems in material science (e.g., determination of boron, carbon, nitrogen, and oxygen impurities in very pure materials such as copper or silicon) and environmental science (e.g., determination of the toxic elements cadmium, thallium, and lead in solid environmental samples). As these problems cannot be solved by NAA, CPAA and NAA are complementary to each other.

CPAA can easily be applied to solid, massive samples with good thermal conductivity and available as foil or sheet slightly thicker than the range (e.g., metals). Special precautions have to be taken for powdered materials and poor thermal conductors. Analysis of liquids and gases is inconvenient.

If spectral interferences can be avoided (multielemental), instrumental analysis is possible (i.e., without radiochemical separation between irradiation of the sample and measurement of the induced activity). In general, an instrumental analysis is possible for analyte elements with low atomic number in a matrix with high atomic number, because the charged particle energy can be chosen just below the Coulomb barrier for the matrix element.

Detection limits down to the  $\mu\text{g}$  per kg level have been attained for the most favorable instrumental analyses (e.g., carbon and nitrogen in molybdenum and tungsten) and for radiochemical analyses (e.g., cadmium and thallium in zinc) at least if no nuclear interferences occur. This is below the concentration levels at which these impurities influence the material characteristics and below the detection limit attainable by more common methods of analysis. A precision (reproducibility) of a few percent is possible at the mg per kg concentration level in the most favorable cases. However, at higher concentration levels the precision will not improve significantly. Many systematic errors can be checked experimentally (e.g., interferences, yield of a radiochemical separation); others can be avoided experimentally (e.g., surface contamination). Systematic errors due to reagent blanks do not arise.

To apply CPAA one needs access to a cyclotron, a radiochemical laboratory, and  $\gamma$ -spectrometry and  $\beta^+$ -counting equipment. The time needed for one analysis is determined by the half-life of the radionuclide induced and whether a radiochemical separation is necessary or not. The inherent complexity and costs are the major drawbacks of CPAA.

CPAA is an independent analytical method (with respect even to NAA or PAA) that is not subject to the same potential systematic errors as optical (AAS, OES) or mass-spectrometric (ICP-MS) analytical methods, which often require sample dissolution prior to measurement (CPAA does not require sample dissolution prior to irradiation). Therefore, CPAA can provide a significant contribution to certification analyses of reference materials (e.g., BCR, NIST).

## Introduction

Photon activation analysis is based upon the reaction of nuclei with high-energy photons such as  $\gamma$ -rays or X-rays. Analogously to neutron activation analysis — which is better known and much more frequently applied than photon activation analysis — the reaction products are normally radioactive. The induced radioactivity, preferably the emitted gamma radiation and characteristic X-rays, is measured with appropriate spectrometers, in basically the same procedure as for neutron activation analysis and activation analysis with charged particles. One difference between the techniques relates to the different natures of the respective product nuclides; after photon activation it is advantageous to employ, in addition to classical gamma-ray spectrometry, low-energy photon spectroscopy using special semiconductor diodes designed for measurement of ‘soft’ photons. This will be explained further in the context of radiation measurement below.

Another difference is in the yield distribution between the product activities: during exposure to thermal neutrons a single reaction type occurs almost

exclusively, namely ( $n, \gamma$ ). In activation with high-energy (say 30 MeV) bremsstrahlung photons several reaction types can occur, the ( $\gamma, n$ )-type being favored, whereas during charged particle bombardment several reaction types can be induced with comparable activity yields.

Data processing is performed in the same way as for neutron activation analysis, although the spectra of photon activated samples look slightly different from those resulting from after neutron or charged-particle exposure.

Photon activation analysis can be regarded as a complementary technique to thermal neutron activation analysis, with some advantages and several drawbacks. Particularly advantageous features of photon activation analysis as compared to neutron activation include:

- The activating radiation source (usually a linear or circular electron accelerator) is smaller, less expensive, and easier to operate than a nuclear reactor normally used for neutron activation.
- Instrumental multielement analyses can be performed, nondestructively in advantageous cases (i.e., large objects).
- Large objects – up to above the size of the human body – can be analyzed nondestructively, where either bulk analyses comprising the entire object or analyses of selected limited spots can be performed.
- Elements can be analyzed with high detection power that cannot be detected by neutron activation, e.g., light elements (deuterium, beryllium, carbon, nitrogen, oxygen, fluorine, silicon, phosphorus) or elements of environmental interest (nickel, thallium, lead, bismuth).

- Matrix problems frequently encountered in neutron activation analysis (excessive matrix activity, inhomogeneous activation due to large absorption cross-sections, etc.) are significantly reduced.

One disadvantage of photon activation analysis is the comparatively poor detection power for several elements, e.g., sodium, vanadium, cobalt, the rare-earth elements. Thus, ultratrace determinations of these elements are barely possible using photon activation. As in other instrumental analytical techniques, photon activation analysis is a relative quantification method and hence needs reference materials with known compositions. (Reference materials are dealt with below.)

A description of photon activation analysis including historical development can be found in the literature (see Further Reading section).

## History

The first photonuclear activation for analytical purposes was performed with radionuclides as the activating radiation source. These applications were reported in the early 1950s, although apparently the first beryllium determinations by photodisintegration were performed in the late 1930s in the Soviet Union. The analytical detection power of photon activation analysis using radionuclide sources is poor and restricted to the analysis of deuterium, beryllium, several fissile nuclides, and a few nuclides that have low-lying isomeric states. Nonetheless, nuclide excitation is still in use.

Later, small static accelerators were used for the analysis of these elements. With the advent of high-energy cyclic electron accelerators (betatron, microtron, linac), the high-energy bremsstrahlung produced by these machines has been used for photon activation. As a result, the list of determinable elements has increased dramatically and, with a few exceptions, now covers the entire periodic table. Some of the light elements (carbon, nitrogen, oxygen) were analyzed in the early 1950s using photonuclear reactions induced by bremsstrahlung from a betatron. A chemical separation is normally involved in the analysis of these elements. A great deal of fundamental work was devoted to this problem during the 1960s (see later).

Along with the maturity of gamma spectroscopy equipment, the extension of the method to heavier elements, as happened in the 1960s, was straightforward.

## Photonuclear Reactions

Shortly after the beginning of photonuclear research in 1934, photoreactions were exploited for analytical purposes as well as for radionuclide production.

### Absorption of Photons by Nuclei

Nuclear reactions induced by electromagnetic radiation can be described – at least for sufficiently low-photon energies – in terms of a two-stage process. Absorption of a photon leads to an intermediate highly excited state of the nucleus. The excitation energy of this so-called compound nucleus can then be released by emission of photons, neutrons, or charged particles.

### De-Excitation of the Nucleus after Absorption of a Photon

The excitation energy may be released by the following processes: (1) Re-emission of a photon with the same energy as the incident photon. This process is called elastic scattering or  $(\gamma, \gamma)$ -reaction. (2) Emission of photons with lower energy. This type of reaction is known as inelastic scattering or  $(\gamma, \gamma')$ -reaction. (3) Emission of neutrons, protons, or composite particles if the excitation energy exceeds the particle separation threshold.

### Photonuclear Reactions Used for Activation Analysis

According to the processes described above, a photonuclear reaction is described by

or symbolically, according to convention,

where T is the target nucleus, P is the activation product, and b is the promptly emitted particle, usually  $\gamma$  or n-type being the most relevant for analytical application. At higher incident photon energies,  $(\gamma, 2n)$ ,  $(\gamma, 3n)$ ,  $(\gamma, p)$ ,  $(\gamma, \alpha)$ , and other reactions can also be induced during photon bombardment. However, these reactions mostly lead to undesirable interference and thus should be minimized through proper selection of the activating energy. In daily laboratory practice, 30 MeV bremsstrahlung has proved optimal for photon activation analysis.

As mentioned above, the first photoactivations were performed with radionuclide sources. Consequently, analytical application was then restricted to nuclides with low neutron binding energies (photodisintegration of  $^2\text{H}$ ,  $^9\text{Be}$ ); nuclides that undergo low-energy photofission (thorium, uranium), being detected by prompt neutron counting; and nuclides that have sufficiently long-lived isomeric states to be counted with some delay after activation.

With the help of high-energy accelerators, photon activation was soon extended to the analysis of

carbon, nitrogen, oxygen, and fluorine, all these being elements with nuclear properties unfavorable for neutron activation analysis. These require chemical separation after photon exposure since their activation products are pure positron emitters. Activation products of heavier elements mostly emit characteristic  $\gamma$ -ray spectra, hence they can be analyzed instrumentally, particularly since high-resolution semiconductor photon spectrometers are now generally available. In some cases, however, a radiochemical separation step must also be included in the analytical procedure for heavier elements, e.g., when the desired analytical signal is interfered with by signals of other components, or in the case of excessive matrix activity background. In this case it can be of advantage to use scintillation spectrometry.

As mentioned earlier, the use of low-energy photon spectrometry is frequently advisable. Among the activation products resulting from photon exposure, neutron-deficient nuclides predominate via the most probable reaction types (see eqn [1])—( $\gamma, n$ ) in particular. While most product nuclides with low atomic numbers decay by positron emission, the electron-capture decay mode dominates among activation products of medium to high  $Z$ , resulting in emission of intense characteristic X-ray spectra. These can be measured conveniently with low-energy photon detectors (see below, Photon spectrometry). In many cases low-energy photon spectrometry offers several advantages when compared to classical  $\gamma$ -measurement.

### Induced Activity and Analytical Sensitivity

The general radioactivation eqn [2] is

$$A = \frac{mN_A h}{A_r} \cdot \left( \int_{E_{th}}^{E_{max}} \sigma(E) \phi_E(E) dE \right) (1 - e^{-\lambda T_i}) e^{-\lambda T_D} \quad [2]$$

where  $A$  is the induced activity,  $m$  the target mass,  $N_A$  Avogadro's constant,  $h$  the isotopic abundance,  $A_r$  the relative atomic mass,  $E_{th}$  the threshold energy,  $E_{max}$  the maximum energy of the bremsstrahlung continuum (equals incident electron energy),  $\sigma(E)$  the energy-differential activation cross-section,  $\phi_E(E)$  the energy-differential photon flux density,  $\lambda$  the decay constant,  $T_i$  the exposure period, and  $T_D$  the decay time.

The achievable product activity depends on the photon energy and flux density of the activating source (Figure 1). Generally, the difference in detection limits among the elements is nowhere near as large as in neutron activation analysis. Typically, the detection limits, assuming purely instrumental analysis, lie between 0.001 and 1  $\mu\text{g}$ , whereas in thermal

**Figure 1** Schematic representation of bremsstrahlung flux ( $\phi(E)$ ), normalized bremsstrahlung continuum ( $f(E)$ ), and photo-cross-section ( $\sigma(E)$ ).

**Table 1** Achievable absolute detection limits in instrumental photon activation analysis

Element	Detection limit ( $\mu\text{g}$ )
Carbon	0.02
Nitrogen	0.02
Oxygen	0.05
Fluorine	0.001
Calcium	0.5
Titanium	0.005
Nickel	0.06
Rubidium	0.2
Zirconium	0.03
Cadmium	0.02
Tin	0.2
Barium	0.1
Samarium	0.005
Gold	0.005
Thallium	0.04
Lead	0.1
Bismuth	10.0
Uranium	0.001

neutron activation analysis the range covers many orders of magnitude. The practical detection limit is often restricted by high matrix radiation background. Furthermore, the large variety of reaction types that may be induced means the analyst has to select carefully the appropriate incident energy for the given task. This is a compromise between maximum analytical activity and minimum interfering activity. For example,

Analytical reaction:  $^{59}\text{Co}(\gamma, n) ^{58}\text{Co}$

Interfering reaction:  $^{63}\text{Cu}(\gamma, xn) ^{58}\text{Co}$

Table 1 lists the achievable analytical detection limits of several elements.

## Radiation Sources

In radionuclide photoactivation,  $^{124}\text{Sb}$   $\gamma$ -ray sources have mostly been used, but others have also been reported, e.g.,  $^{24}\text{Na}$  or  $^{60}\text{Co}$ . The use of isotopic sources for photon activation analysis is of limited value and is restricted to a few appropriate cases.

## Electron Accelerators

The disadvantages of isotope sources mentioned above can be circumvented by using bremsstrahlung for photoactivation. Accelerator-produced high-energy electrons are directed on to a heavy-metal target, preferably tantalum, tungsten, gold, or platinum. In this target, high-energy bremsstrahlung is produced as the electrons are decelerated in the Coulomb fields of the target nuclei.

The achievable photon flux densities usually exceed those of radionuclide sources by orders of magnitude. Moreover, the effective cross-section is significantly enlarged since the bremsstrahlung is continuous with electron energy (see **Figure 1**). Finally, much higher photon energies are produced than are obtainable with any isotope source. Hence, photonuclear reactions can be induced with bremsstrahlung, whereas  $\gamma$ -rays, with a few exceptions, can achieve only isomeric-state excitation.

One has to distinguish between linear and circular electron accelerators according to the geometry of the particle trajectories. The different accelerators are further defined by their operation mode, namely static and cyclic devices. In static accelerators electrons are accelerated by a constant high-voltage potential. The maximum achievable particle energy is directly dependent upon the maximum high voltage of the individual machine. Among static machines, only van de Graaff accelerators sometimes have been used for photon activation.

In cyclic accelerators (linacs, betatrons, microtrons) electron energies are achieved by multiple application of comparatively low voltage to the electrons. The maximum achievable energy is dependent on various parameters. Practical experience suggests that accelerators producing energies higher than, say, 50 MeV are unnecessary. Moreover, as explained above, these energies lead to frequent interfering reactions. Analytical requirements are best met by machines that provide  $\sim 30$  MeV bremsstrahlung at an average electron beam current of at least  $100\text{ }\mu\text{A}$ . The output energy should be freely selectable so that interfering higher-order reactions can be discarded by adjustment of the incident energy below the respective threshold energy.

Of these accelerators, two types have mostly been used for photon activation analysis, namely the linear accelerator (also called linac) and the microtron. These and other accelerators will not be described in detail here since normally the analyst is engaged in the sample handling, activity measurement, and data processing rather than in the operation of the radiation sources, which is usually done by separate operating personnel.

## Activation with Photoneutrons

Photoneutrons are produced at considerable flux densities in the heavy metal of the bremsstrahlung converter. For example, in the linear accelerator used by the authors, a thermal neutron flux density of some  $10^{10}\text{ cm}^{-2}\text{ s}^{-1}$  has been produced in the tantalum converter during normal operation (30 MeV,  $150\text{ }\mu\text{A}$ ). This appears a relatively poor flux density compared to that of a standard nuclear research reactor. Nevertheless, in advantageous cases trace analyses can be performed. For example, routine analyses of several elements in air-dust samples were carried out by activation with photoneutrons (see below). Normally, however, the photoneutron flux is analytically negligible, whether as an analytical tool or as a source of interference.

## Sample Preparation and Irradiation

Basically, any kind of material – solid, liquid, or gaseous, organic or inorganic – can be analyzed by photoactivation. However, in preparing analytical samples, precautions are necessary against damage to the material, e.g., during long-period bremsstrahlung bombardment of organic matrices. Losses of components radiolytically volatilized during bremsstrahlung exposure sometimes have to be taken into account, e.g., mercury evaporation.

Typically, a set of samples of a few milligrams up to gram amounts are individually wrapped in aluminum foil and packed into the irradiation container. Pneumatic transfer systems are usually used for transport of samples to the irradiation position. **Figure 2** shows a schematic representation of a typical irradiation position. The sample rabbit is rotated by air-blow so as to obtain a quasihomogeneous activity distribution. Excessive heat is removed from the sample by the air-jet. Exposure periods depend upon the half-lives of the expected product activities; for a typical multielement trace analysis, irradiation times of a few hours are sufficient.

Other modes of sample preparation will be described below in the application examples.

**Figure 2** Typical bremsstrahlung exposure position; schematic representation. 1 = Sample and reference material; 2 = sample rabbit; 3 = tangential airflow injection inlet; 4 = pneumatic tube; 5 = compressed air inlet for sample rabbit retransfer; 6 = bremsstrahlung converter assembly; 7 = electron beam window (Ti); 8 = accelerator tube.

## Photon Spectrometry

Activity measurements using radiation other than electromagnetic have been performed in only a few cases; only photon spectrometry is discussed here.

Two basic principles of photon counting have been used: detection by scintillators exploiting the radio-luminescence effect, and detection by semiconductor crystals. These detectors and the subsequent spectrometry electronics will not be discussed here. Spectrometry during neutron and photon activation analysis is performed in basically the same way. One difference is due to the different nature of the product nuclides in the respective activation techniques.  $\beta^-$ -Emitters are mainly produced by neutron activation, whereas neutron-deficient nuclei predominate after photon exposure. Thus, scintillation spectrometry after neutron activation has now more or less been abandoned. In photon activation analysis of the light elements, however,  $\gamma$ - $\gamma$  coincidence spectrometry using two NaI(Tl) crystals in sandwich geometry is used (see Figure 3). Here the background radiation can be suppressed to negligible level by measuring the  $\beta^+$  annihilation quanta simultaneously. Furthermore, as briefly mentioned earlier, low-energy photon spectrometry is recommended for multicomponent spectra measurement after photon activation. Flat ( $\sim 10$  mm thick) planar germanium or silicon diodes are used, equipped with

**Figure 3** Schematic representation of a  $\gamma$ - $\gamma$  coincidence spectrometer. 1 = NaI(Tl) crystal detector; 2 = irradiated sample; 3 = spectroscopy amplifier plus single channel analyzer (adjusted to screen the 511 keV annihilation peak); 4 = coincidence unit; 5 = recording instrument, e.g., multichannel analyzer.

thin beryllium entrance windows so as to allow measurement of soft photon radiation, e.g., characteristic X-rays. In several cases, the analysis of this energy region, say from 5 to 190 keV, offers some advantage compared with classical  $\gamma$ -ray spectrometry.

## Analytical Procedure

### Reference Materials

Photon activation analysis, as well as other instrumental techniques, is generally quantified by comparison of activities in the sample with those in a reference material of known elemental composition that was irradiated simultaneously. In photon activation analysis this is necessary particularly because some accelerator parameters and nuclear data for the photoreactions involved are either unknown or not precisely determinable. In addition, some machine parameters of the accelerator cannot be assumed constant throughout the exposure period and might show uncontrolled variation. The use of

reference materials irradiated simultaneously with the samples implicitly accounts for these parameters. Primary standards, i.e., pure elements or substances synthesized from stoichiometrically well-determined compounds, are used for quantification through comparison of the activities after activation. Certified reference materials are also analyzed to ascertain the total accuracy of the results. Frequently it is useful to provide a matrix-inherent or additive internal standard that serves as a flux monitor. The integral quality of the analytical data (in terms of accuracy and precision) is thereby significantly improved.

### Analysis of Light Elements

One special feature of photon activation analysis is the analysis of light elements such as carbon, nitrogen, oxygen, and fluorine. The analytical procedure in this case is essentially different from that in instrumental multielement analysis. This is due to the fact that the prominent photonuclear reactions of these elements, e.g.,  $^{12}\text{C}(\gamma, n)^{11}\text{C}$ , yield pure  $\beta^+$ -emitters exclusively and thus emit no characteristic photon radiation by which they might be detected. Hence, after activation these elements have to be separated radiochemically from the sample matrix prior to annihilation radiation measurement. In the case of carbon, nitrogen, and oxygen, this is usually performed by heat extraction. Fluorine separations are normally carried out by distillation as hexafluorosilicic acid. Nondestructive or instrumental analyses of the light elements are possible only in exceptionally favorable cases, namely if the activated matrix does not emit positron radiation at significant level at the time of measurement. However, currently photon activation techniques are under development that, with help of improved high-performance hardware and software, will enable instrumental analyses of light elements in multicomponent samples through photon activation.

### Analysis of Heavier Elements; Multielement Analysis

High-resolution photon spectrometry with semiconductor detectors has normally been used for multielement photon activation analysis. One generally strives for a purely instrumental or, if possible, nondestructive procedure. In several cases, however, a radiochemical separation step is unavoidable and sometimes advantageous.

## Examples of Analytical Procedures

### Radiochemical Analysis of Carbon in Molybdenum

A typical analytical procedure, such as that for carbon in molybdenum, can be summarized as follows.

About 1 g of material was placed in the rabbit. Pieces of graphite foil were put on both sides of the sample. These served as primary reference material. The rabbit was then transferred to the irradiation position through a pneumatic tube system. After 20 min exposure to 35 MeV bremsstrahlung (mean electron beam current  $80\text{ }\mu\text{A}$ ) the sample was transported back to the radiochemical laboratory and unpacked. The surface contamination was then removed by etching with aqua regia. The sample was placed in an alumina crucible that contained a mixture of 87.5%  $\text{Pb}_3\text{O}_4$  and 12.5%  $\text{B}_2\text{O}_3$  as oxidizing agent plus a piece of iron to initiate and support the melting process. The crucible was heated in a high-frequency furnace with an output power of 1 kW at a frequency of 10 MHz. The sample-borne carbon thus volatilized as  $^{11}\text{CO}_2/^{11}\text{CO}$  was transported by an argon flow from the melted sample. Inactive carbon dioxide originating from the iron flux served as an inactive carrier. The gas mixture was cleaned by a glass wool filter and led through a tube containing Schütze reagent (iodide pentoxide on silica gel) to oxidize radiocarbon monoxide to the desired dioxide. Finally,  $^{11}\text{CO}_2$  was absorbed with potassium hydroxide and then, after a total decay period of 30 min, counted in the coincidence spectrometer described above. A decay curve was recorded to ascertain the radiochemical purity of the sample. The reference material was then counted without a separation step. The detection limit was  $0.02\text{ }\mu\text{g}$  under the described conditions.

### Fluorine in Seawater

This procedure is fundamentally different from that described above not only because of the water matrix but because fluorine cannot be mobilized by heat extraction, but requires distillation. A typical procedure is as follows.

Three milliliters of seawater was freeze-dried. Artificially synthesized seawater containing known amounts of NaF was used as reference material and treated accordingly. In order to avoid first-order interference by sodium through the reaction  $^{23}\text{Na}(\gamma, \alpha n)^{18}\text{F}$ , the linear accelerator bremsstrahlung radiation was used at 22 MeV maximum energy so as to stay below the threshold energy of this reaction. The exposure period was 20 min. After dissolution of the sample in distilled water, the other halogens were removed by silver nitrate precipitation. Radiofluorine was then distilled as  $\text{H}_2\text{Si}^{18}\text{F}_6$  with some inactive sodium fluoride added as a carrier for quantitative vapor distillation. Finally,  $\text{PbCl}^{18}\text{F}$  was precipitated and then counted with a  $\gamma$ - $\gamma$  coincidence sodium iodide spectrometer. Data evaluation was performed

by a decay-curve analysis program. The overall detection limit under the experimental conditions described was found to be 0.03  $\mu\text{g}$  of fluorine.

### **Radiochemical Multielement Analysis of River Water**

Photon activation analysis is suited to water analysis because practically unlimited volumes can be irradiated, thus enhancing the total sensitivity and avoiding solidification prior to analysis; any pretreatment of water, e.g., evaporation, entails the danger of contamination or undesirable loss of components. Water can be analyzed without pretreatment using photon activation as follows.

Water (1.5 l) was brought in a storage vessel and 200  $\mu\text{g}$  of each of scandium and samarium were added as nitrate solution to serve as internal standards. The sample was then irradiated with 30 MeV bremsstrahlung (mean electron beam current 150  $\mu\text{A}$ ) from an electron linear accelerator for 5 h in a 0.7-l flow-chamber under slow continuous cyclic flow. Thereafter, the components of interest (Sc, Cr, Mn, Co, Ni, Cu, Zn, As, Y, Zr, Nb, Mo, Cd, Sn, Sb, I, Ba, Tl, Pb, and U) were separated by a sulfur-substituted cellulose-based sorbant filter switched into the flow cycle after activation. This sorbant was then dried in a microwave furnace and pressed to a thin (1 mm thick) pellet. Product activities were counted with a large coaxial germanium detector (where  $^{44\text{m}}\text{Sc}$  was used as an internal bremsstrahlung flux monitor), and with a planar germanium low-energy photon diode (where 103 keV of  $^{153}\text{Sm}$  served as an internal standard). Results were obtained by automatic spectrum processing; data evaluation was achieved with personal computer programs. The results were in good agreement with analyses performed in parallel using different procedures.

### **Radiochemical Analysis of Rock Material**

Owing to the nature of the matrix analyzed, a radiochemical separation step is sometimes required in the analytical procedure, e.g., in the case of severe interference of the analyzed signals by matrix activity. The analytical quality of the results (in terms of accuracy, precision, and sensitivity) is severely degraded if lower-energy gamma peaks (say less than 511 keV) to be evaluated are superimposed upon a huge Compton background continuum, or if the signal is interfered by other strong peaks in the close vicinity, in the worst case overlapping the desired signal. In the rock material analysis described the analyzed  $\gamma$ -ray line of  $^{57}\text{Ni}$  (1378 keV) originating from trace amounts of nickel suffered from the closeness of the 1369-keV line of  $^{24}\text{Na}$  due to

magnesium present as a major component in the sample. Therefore, radionickel was separated from the matrices of the samples (USGS standard rocks with recommended element contents). After exposure to 30 MeV bremsstrahlung at a mean electron beam current of 70  $\mu\text{A}$  for 2 h the samples (400 mg each) were transferred to platinum crucibles, together with 10 mg nickel carrier. This mixture was fused with 4 g sodium carbonate, and then dissolved in concentrated hydrochloric acid; the hydroxides were then precipitated with ammonia. After purification by redissolution and reprecipitation nickel was precipitated as glyoximate and formed into a small disk that was then subjected to high-resolution gamma spectrometry. Primary standards served as reference materials. The agreement with the comparison data was satisfactory. An overall sensitivity of  $\sim 50$  ng of nickel under the described conditions was found.

### **Instrumental Air-Dust Analysis**

Review of the analytical literature indicates the analysis of airborne particulate matter to be one of the most frequent applications for photon activation analysis.

Air-dust samples from different locations in the Federal Republic of Germany were taken in high-volume samplers. Cellulose nitrate membrane filters were used for particulate collection. The filter was divided into several subsamples to be analyzed comparatively by 12 laboratories using eight different techniques, photon activation being one of them. Internal standard solutions of 50  $\mu\text{g}$  scandium and 10  $\mu\text{g}$  samarium (see above, River water analysis) were dropped onto the sample, which was then dried and dissolved in acetone. Cellulose powder (150 mg) was then added to serve as a binding matrix for the pellet pressed after stirring to dryness. These were placed in a rabbit, transported to the irradiation position of a linear electron accelerator by pneumatic transfer, and irradiated with 30-MeV bremsstrahlung. After 4 h exposure and a cooling period of 2 days, the activation products of the sample were measured with the spectrometers described above; the resulting spectra were processed as already described (see above, River water analysis). Na, Mg, Si, Cl, K, Ca, Ti, Cr, Fe, Co, Ni, Zn, As, Se, Br, Rb, Sr, Y, Zr, Nb, Mo, Cd, Sn, Sb, I, Cs, Ba, Ce, Nd, Tl, Pb, and U were analyzed by their respective photoreaction products; vanadium and manganese were determined using  $^{52}\text{V}$  and  $^{56}\text{Mn}$ , respectively, produced through activation by photoneutrons. In comparing the results of all techniques applied, good agreement of the photon activation data with the joint consensus values was reported.

### **In vivo Analysis of Trace Metals in Humans**

During cancer radiotherapy using a betatron, several metal components were analyzed *in vivo* in the treated body regions. Patients were irradiated repeatedly (each exposure period was 10 min) at a distance of 1 m from the bremsstrahlung converter. Immediately thereafter, the treated body regions were measured with a large-volume germanium detector. Mg, Cl, Ca, Cr, Fe, Ni, Zn, Sr, Sn, and Pb were analyzed. No significant differences in the element concentrations were apparent during the treatment, which lasted for several weeks. However, qualitative and quantitative differences became discernible regarding the type of disease and the mode of treatment.

### **Nondestructive Analysis of an Ancient Musical Instrument**

In studying antiquities and objects of art, nondestructiveness is generally essential. A baroque silver trumpet (early eighteenth century) from a collection of 12 in total was analyzed nondestructively by photon activation. The primary objective was the characterization of the basic alloy (Ag/Cu) since several parts of the instrument had to be replaced. An alloy had to be used for restoration that was as similar as possible to the original material since it was intended to make the trumpet chorus playable, which necessitated providing compatible acoustic properties of all instruments. Copper sheet disks that served as flux monitors were attached to the areas of interest, which were then activated with bremsstrahlung from an electron linear accelerator. Maximum energy of 16 MeV was selected in order to avoid the production of undesirably long-lived  $^{105}\text{Ag}$  activity in the matrix alloy. Within the selected irradiated areas, spots of several square millimeters were screened with a lead collimator and measured with a coaxial germanium detector (see Figure 4). Thereafter, a piece of silver alloy sheet with known composition was activated and measured as a primary reference material. Processing of the resulting  $\gamma$ -ray spectra and quantitative data calculation were performed with appropriate personal computer programs.

With these analytical results, a silver alloy with a very similar composition could be found. After restoration, acoustic examination yielded excellent homogeneity of the chorus. The collection can now serve its original purpose of being played at special ceremonial events.

### **Fields of Application**

Since there is no limitation of the method with respect to the matrix studied, there is a broad spectrum of applications in the field of material science.

**Figure 4**  $\gamma$ -Ray spectrum of an ancient silver trumpet after exposure to 30 MeV bremsstrahlung with several component signals marked; most of the others are due to the matrix silver.

Photon activation analysis has primarily been applied in the areas of geo- and cosmochemistry, oceanography, environmental science, industrial raw- and end-product analysis, high-purity material studies, organic material/medical and biological material analysis, forensic science, art and archaeology, certification of candidate reference materials.

# ADHESIVES AND SEALANTS

**R G Leonard and K Quigley**, Henkel-Loctite, Tallaght, Dublin, Republic of Ireland

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

The use of adhesives/sealants in both the industrial and consumer spheres has increased dramatically in the past 20 years. In the industrial segment, both reactive and nonreactive systems are used in a wide variety of applications. The increasing use of reactive systems has, however, tended to overshadow that of the nonreactive systems. Most prominent amongst the reactive systems favored in industrial applications are anaerobic sealants (methacrylate ester based), instant adhesives (alkyl cyanoacrylate ester based), acrylic (toughened) adhesives, epoxy resin adhesives, polyurethane/isocyanate-based adhesives, silicone adhesives/sealants, and phenolic resin adhesives.

In the case of nonreactive type of systems favored for the industrial market, the most widely used types are (1) hot melt adhesives, (2) solvent-based adhesives, and (3) pressure-sensitive adhesives.

In the hot-melt type, two principal polymer types are used: polyolefin and ethylene co-polymer based; and polyester and polyamide type. In the solvent-based type, the most prominent are neoprene (polychloroprene)-based solvent and latex types, and polyvinyl acetate emulsions. For pressure-sensitive adhesives, the most favored are acrylic adhesives and butyl rubber/polyisobutylene types.

For the analytical laboratory required to analyze a sealant/adhesive formulation a considerable challenge is posed by the wide range and considerable complexity of many of the adhesive types. Undoubtedly, the reactive formulations pose the greatest challenge. This is particularly evident in the case of the redox-cured methacrylate resin-type formulations (anaerobic products), which are widely used in threadlocking, sealing, and retaining applications in the engineering and machinery industries.

## Analysis of Anaerobic Sealants/Adhesives

These anaerobic sealants are essentially liquids that remain stable (i.e., in the original liquid form) in the presence of oxygen. When confined between two closely fitting metal parts (e.g., nut and bolt), thereby excluding oxygen, the monomeric constituents in the

liquid polymerize. This polymerization is rendered especially favorable if the metal is able to catalyze the redox-based 'cure' process. These sealants consist of a complex mixture of methacrylate (or less commonly, acrylate) esters, free-radical initiators, accelerators, free-radical inhibitors, metal-chelating agents, plasticizers, thickeners, inert fillers, pigments, and dyestuffs. These constituents are very carefully adjusted to give the correct balance between speed of cure and stability.

A rather simplified schematic of the redox-based cure chemistry of anaerobic sealants is shown below in **Scheme 1**.

The reaction scheme highlights the key catalytic role played by the active metal surface. In essence, the metal functions as an intrinsic component of the cure system.

### Typical Reactive Monomers and Resins

The polymerizable methacrylate monomer is typically the dominant component in the composition. The monomer may be present as a single component or in a mixture. Some examples of commonly used methacrylate esters are shown in **Schemes 2–5**.

### Typical Cure Promoters and Stabilizers

The cure systems typically incorporate an organic peroxide, an organic reducing agent, and an organic acid. The preferred peroxides include cumene hydroperoxide (CHP), *t*-butyl hydroperoxide, *t*-butyl perbenzoate, and dibenzoyl peroxide. The organic reducing agents are typically aromatic amines such

**Scheme 1**

**Scheme 2**

as *N,N*-dimethyl-*p*-toluidine and 1,2,3,4-tetrahydroquinoline. Occasionally, other reducing agents including acylhydrazines and mercaptans may also be used.

A variety of organic acids including *p*-toluenesulfonic acid and maleic acid have been used as cure accelerators. The other essential components in any anaerobic or acrylic formulation are the stabilizing components that are required to prevent any premature polymerization, either during manufacture or in subsequent storage of the formulations prior to use. The free-radical inhibitors may include phenolic compounds such as hydroquinone, *p*-methoxyphenol, pyrogallol, etc. Cure retarders may also be used as typified by 1,4-benzoquinone and 1,4-naphthoquinone.

Metal-sequestering agents are sometimes incorporated at low levels (10–100 mg per kg) to preclude any problems arising from trace metal contamination. Ethylenediaminetetraacetic acid (EDTA) and its various analogs tend to be the preferred type.

### Characterization of Monomer/Resin Components

The presence and/or identity of the polymerizable component(s) in a formulation are routinely

Poly(ethylene glycol) dimethacrylate

Scheme 3

Trimethylolpropane trimethacrylate

Scheme 4

Ethoxylated bisphenol (A) dimethacrylate

Scheme 5

established by a combination of nuclear magnetic resonance (NMR) and infrared (IR) spectroscopy together with gas chromatographic (GC) and liquid chromatographic (LC) techniques. In the case of anaerobic sealants, which cure through a room-temperature redox-initiated mechanism, the monomeric components are typically mono-, di-, or tri-functional methacrylate esters or a combination of these. The  $^1\text{H}$  and proton decoupled  $^{13}\text{C}$  NMR spectra of triethyleneglycol dimethacrylate (TRIEGMA) Scheme 6 recorded on a 270 MHz FT-NMR instrument are shown in Figures 1 and 2, respectively. This monomer is used extensively in anaerobic products.

The proton NMR spectrum shows the methyl substituents from the methacrylate end groups at 1.9 ppm (relative to tetramethylsilane (TMS)). The methylene groups bonded to ether oxygen appear in

Triethyleneglycol dimethacrylate

Scheme 6

Figure 1  $^1\text{H}$  NMR spectrum (270 MHz) of triethyleneglycol dimethacrylate in  $\text{CDCl}_3$ .

the range 3.6–3.8 ppm, while the methylene groups bonded to ester oxygen are found at 4.3 ppm (relative to TMS). The terminal olefinic protons give resonances at 5.6–6.1 ppm.

The  $^{13}\text{C}$  spectrum of the TRIEGMA monomer shows the following resonances: the methyl substituents at 18 ppm, ester methylene groups at 64 ppm, ether methylene groups at 69 and 71 ppm, olefinic carbon atoms at 126 and 137 ppm (terminal carbon atom), and carboxyl carbon atoms at 168 ppm.

Such multifunctional esters are used to promote the formation of a rigid cross-linked structure on polymerization. Quantitation of these esters is normally based on GC analysis using an internal standard. Either narrow or wide bore capillary columns may be used. In the case of ultraviolet cure-initiated formulations, the use of higher-molecular mass urethane–methacrylate resins such as **Scheme 7** is involved.

The 270 MHz  $^1\text{H}$  NMR spectrum of the urethane resin includes resonances typical of methacrylate esters as outlined above. In addition to these, bands due to alkyl groups (1.0–1.4 ppm range), methyl substituents on aromatic rings (2.2 ppm), and

aromatic protons (7–8 ppm) are present. The  $^{13}\text{C}$  spectrum of the same urethane resin shows, in addition to the methacrylate resonances, resonances associated with alkyl substituents (17 ppm), aromatic rings (110–140 ppm), and the urethane carboxyl moiety (154 ppm).

Such resins may be used in combination with the simpler methacrylate monomers to improve the performance of the cured product. Their relative involatility and the presence of a UV-absorbing chromophore make LC the preferred approach for analysis. Again the use of an internal standard is favored for quantitation purposes.

### Characterization of Cure/Stabilizer Systems

The performance of modern adhesive/sealant formulations is critically dependent on the cure system used. This must be judiciously balanced in order to give the desired performance, especially with respect to cure speed, together with a viable stability for the packaged product. The cure promoters are present at relatively low concentration ( $\sim 1\%$  w/w). It is essential therefore that the appropriate analytical methods and techniques are available to identify and quantify these reactive components.

Thin-layer chromatography (TLC) is a fast, inexpensive technique well suited to adhesive/sealant analysis. Unlike many analytical techniques, little advanced instrumentation is required, apart from a UV/visible light source for some tests. In addition, sample preparation is generally minimal. Furthermore, in conjunction with specific spray reagents, TLC can be rapidly used to confirm the presence of organic peroxides, reducing agents, organic acids, and photoinitiators (if a UV-curing formulation is involved). The presence of certain free-radical inhibitors can also be established by TLC.

A typical TLC procedure involves the use of commercially available precoated plates (silica gel F254). Direct application of dilute solutions of the adhesive products is followed by development of

**Figure 2**  $^{13}\text{C}$  NMR spectrum (270 MHz) of triethyleneglycol dimethacrylate in  $\text{CDCl}_3$ .

Urethane–methacrylate resin

**Scheme 7**

the plate in an appropriate solvent system. The curatives in the formulation will separate from the other components (and from each other) as the chromatogram is developed. Subsequent analysis of the TLC plate is carried out with the use of specific spray reagents for visual detection of the components. A common curative used in adhesive formulations is the peroxy initiator CHP. A TLC plate containing the substance is sprayed with an aqueous methanolic solution of *N,N*-dimethyl-*p*-phenylenediamine dihydrochloride and heated gently. The presence of CHP is confirmed by the appearance of purple spots on the plate, corresponding in  $R_f$  value with a standard solution of CHP on the same plate. Aromatic amines are also components in adhesive/sealant catalyst systems. The spray reagent used to detect these compounds consists of a dilute aqueous solution of iron(III) chloride and potassium hexacyanoferrate(III). The presence and chemical identity of the amines (and other appropriate reducing agents) can be determined by the appearance of variously colored spots with different  $R_f$  values on the chromatogram.

In a similar fashion, acidic species present in some catalyst systems can be determined on TLC plates by the use of a dilute ethanolic solution of 2,6-dichlorophenolindophenol sodium salt.

Free-radical stabilizers such as hydroquinone, *p*-benzoquinone, *p*-toluquinone, chloranil, and 1,4-naphthoquinone can be detected by reaction with rhodanine and ammonia (spot test or TLC method) to give a colored complex.

While the above procedures are useful for qualitative work, commercially available TLC plate scanners (with varying levels of automation) can be used for quantitative assays.

In the case of radiation-curable (e.g., UV) adhesives, TLC represents a very useful screening test for the presence of several characteristic photo-initiators, e.g., benzophenone, 2,2'-diethoxyacetophenone, 1-benzoylcyclohexanol, and 4,4'-dimethylaminobenzophenone (Michler's ketone).

GC and LC procedures may then be used to confirm the TLC results, as well as being used to quantify the level of each component. These chromatographic techniques, moreover, have the added advantage that they may also be used to identify and quantify the monomeric and plasticizer components of the formulation (Figures 3 and 4). As stated previously, either narrow or wide bore capillary columns may be used for GC analysis. Preferred stationary phases are OVI (poly(dimethylsiloxane)) and OV17 (poly(phenylmethylsiloxane)). Flame ionization is the usual mode of detection, but where unambiguous confirmation of peak identity is required, a gas chromatograph coupled to a bench-top mass spectrometer may be used (GC-MS).

In LC analysis, the usual approach adopted is to employ the reversed-phase mode using a  $C_{18}$ -type stationary phase. A typical eluent would be a binary phase based on methanol or tetrahydrofuran with water. The latter solvent mixture has the advantage that the strong solvent capability of the tetrahydrofuran readily dissolves the polymeric components

**Figure 3** GC trace of a typical anaerobic sealant: A, carboxylic acid; B, organic peroxides; C, internal standard (I); D, methacrylate ester; E, aryl hydrazine; F, methacrylate ester; G, internal standard; H, methacrylate ester; I, methacrylate ester; J, plasticizer; K, methacrylate ester; L, methacrylate ester.

usually incorporated in these formulations. A variable wavelength UV/visible detector is used, and when quantitation is required the compound is monitored at its wavelength of maximum absorption.

The peroxide content of sealants/adhesives is normally established by an iodometric titration approach that involves reducing the peroxy group with iodide ion in an acidic medium and titrating the liberated iodine with standard sodium thiosulfate. The endpoint is established by potentiometric detection with a platinum-reference electrode combination. Aromatic amine content is determined by titration with perchloric acid in acetic acid as solvent. The endpoint is established using potentiometric detection with a glass-reference electrode combination. The latter electrode combination is also favored for quantitation of the acidic components of the formulation. Dilute alkali hydroxide or tetrabutylammonium hydroxide are used as titrants in aqueous or nonaqueous media, respectively. In the case of the organic peroxides, an important test applied to the incoming materials is an assay procedure based on their measured active oxygen content. This is routinely determined using a titrimetric procedure involving iodometric analysis. This procedure although well established, is relatively time consuming. Recent studies have confirmed that several of the

more frequently used commercial organic peroxides may be assayed by chromatographic techniques, e.g., GC and reverse-phase liquid chromatography (RPLC) as appropriate. Accuracy and precision compare favorably to the classical titrimetric approaches. The principal advantages are the relatively short analysis time as compared to the conventional approach. In the case of the GC assay, the use of an on-column injection technique is necessary to prevent thermal decomposition of the peroxide in the injection port.

### Viscosity Modifiers and Fillers

Viscosity modifiers, usually referred to as thickeners, are used in varying concentrations throughout the range of sealants and adhesives. They span a diverse range of chemical structures. Some of the more commonly encountered thickeners include poly(alkyl methacrylates) – homo and/co-polymers; poly(alkyl acrylates) – homo and/co-polymers; polystyrene; acrylonitrile-butadiene-styrene co-polymers; poly(vinyl acetate); fumaric or maleic acid-based polyesters.

The chemical identity of such materials may readily be confirmed by IR spectroscopy. The initial step involves isolation of the thickener from the formulation matrix. Typically, the adhesive sample is diluted with chloroform to reduce the viscosity. This

**Figure 5** FTIR spectrum of co-polymer of methyl methacrylate and butyl methacrylate.

solution is then subjected to dropwise addition of a polar solvent such as methanol until the thickener is fully precipitated out of solution. After careful drying to remove all traces of solvent, the sample can be analyzed by Fourier transform IR (FTIR) or dispersive IR spectroscopy. The IR spectrum of an acrylic thickener identified as a methyl methacrylate/butyl methacrylate co-polymer is reproduced in **Figure 5**.

Fillers and thixotropic agents are used widely throughout the various acrylic sealant and adhesive products. Fillers also form a significant component of epoxy-based adhesives. For example, if it is necessary to identify the filler used in the hardener component of an epoxy product, the isolation sequence involves initial centrifugation of the product to isolate the crude filler component. The latter is then washed repeatedly with acetone and dried thoroughly. The fine dry powder may then be used to prepare a standard KBr disk for IR analysis.

## Some Useful Analytical Techniques in the Analysis of Industrial Adhesives and Sealants

### Thermal Analysis

Differential scanning calorimetry (DSC) can be used to generate cure profiles of certain adhesive producers. For example, in the electronics assembly business, epoxy-based chipbonding products are used to hold components on to printed circuit boards prior to the automated soldering process. These adhesives are formulated with heat curatives, i.e., they are designed to harden on application of heat. As such, the heat curing profile of these materials can be examined by DSC. The polymerization exotherm detected for a typical epoxy-based chipbonder is shown in **Figure 6**. The heat of reaction, together with peak temperature and other details, can be obtained from this trace. This type of analysis is useful,

**Figure 6** Cure profile of typical chipbonder product (DSC scan).

not only for product monitoring, but as an aid to product development work where different cure profiles may be required to match specific applications.

A further use of DSC in this area is the detection of incomplete (residual) curing in solid samples. A thermally curable epoxy adhesive that has not been fully cured will polymerize as the sample is heated in the calorimeter. This polymerization will give rise to a small exotherm that can be used to estimate the degree of cure in the original sample.

Finally, DSC is used in the broader area of polymer evaluation to measure glass-transition temperature, degree of crystallinity, decomposition profile, etc. Current computer control and storage facilities available with thermal analysis equipment allow data to be comprehensively evaluated, reanalyzed, and compared, reducing the need for repeat analyses.

Thermogravimetric analysis (TGA) is a technique whereby weight changes in a sample can be continuously monitored with respect to temperature. TGA can be used to look at weight losses associated with the polymerization of an adhesive product, or to determine percentage volatiles released from a cured product during thermal cycling.

**Figure 7** TG curve (room temperature to 600°C) for a chipbonding product to determine filler content.

The technique can also be used to determine mineral filler contents of certain products. In this case, a sample is heated gradually to a high temperature and maintained at this temperature for a period to ensure complete ashing. A typical thermogram obtained for a chipbonding product is shown in **Figure 7**. The sample was heated from room temperature to 600°C, and held at the final temperature for 30 min. The resultant stable baseline obtained after complete combustion is used in the calculation of filler content for the sample (13.7% w/w).

### Gel Permeation Chromatography

Gel permeation chromatography (GPC) or size-exclusion chromatography (SEC) is a favored technique for the analysis of polymers and oligomeric compounds. GPC separates sample molecules in the mobile phase on the basis of their effective size. In most cases molecular size can be correlated directly to molecular mass. For the analysis of organic materials the column(s) is packed with a highly cross-linked spherical polystyrene/divinyl benzene matrix with a tightly controlled pore diameter. Any sample molecules that are smaller than the pore size can diffuse into and out of the pores, whereas sample molecules larger than the pores are effectively excluded. As a result, larger molecules elute more rapidly than small molecules. The separation is thus essentially mechanical in nature, rather than chemical as in other forms of chromatography. All molecules larger than the pores elute first and at the same retention time. The smallest molecule that cannot penetrate the pore defines the exclusion limit of the column. Molecules smaller than a certain size have equal access to the pores and so they elute together at the total permeation volume or dead volume. Molecules between these extremes are separated in order of their respective molecular sizes.

**Figure 8** GPC trace of acrylate process oligomer.  $M_p = 2029$ ;  $M_n = 1534$ ;  $M_w = 1862$ ;  $M_z = 2272$ ;  $M_w/M_n$  (polydispersity) = 1.213.

In the analysis of a sample of unknown molecular mass or molecular mass distribution, the first step is to generate a calibration plot ( $\log M_r$  versus elution volume or time) using a set of narrow disperse standards of known molecular masses. The function giving the best fit to the plot is computed and the sample is then analyzed against this calibration function.

In this manner, the number average molecular mass ( $M_n$ ), the mass average molecular mass ( $M_w$ ), the peak molecular mass ( $M_p$ ), and the polydispersity ( $M_w/M_n$ ) may be calculated.

Polystyrene calibration standards are most frequently used, and with polymers of different chemical structure, molecular masses are reported relative to polystyrene.

The GPC trace and computed molecular masses obtained for an acrylate process oligomer are reproduced in **Figure 8**.

GPC is also a very useful technique for characterizing the molecular mass range/distribution of the various organic polymers and co-polymers used as thickeners in anaerobic, acrylic, and radiation-curable adhesives. The base polymer, tackifying resin, and petroleum wax components of hot-melt type adhesives may also be characterized in a similar manner.

The principal limiting factor is solubility, but the use of strong solvents, e.g., tetrahydrofuran, extends the applicability of this technique. Solubility problems may also be overcome by the use of elevated temperatures. Effective high-temperature GPC requires that all the key components – injector, columns, and detector – be temperature controlled. Commercial systems embodying these concepts are available.

### Pyrolysis Gas Chromatography

Pyrolysis GC is an analytical technique whereby complex involatile materials are broken down into smaller volatile constituent molecules by the use of

very high temperatures. Polymeric materials including cured sealants and adhesives lend themselves very readily to analysis by this technique. Essentially, a fingerprint uniquely characteristic of the original material is obtained.

In combination with IR analysis, pyrolysis GC is particularly useful in the following areas:

1. Characterization of polymeric thickeners used in the formulation of sealants and adhesives. Polymers of this type are frequently used to provide protective coatings – in rust-preventative products for example.
2. Characterization of plastic packaging materials.
3. Identification of cured adhesives, by generating pyrogram ‘fingerprints’ for selected adhesives.

Pyrolysis GC is an especially valuable and informative technique when coupled with mass spectrometric detection, which facilitates identification of the pyrolysis products.

### Atomic Spectroscopy

Atomic spectroscopy (including atomic absorption spectrometry, atomic emission spectrometry, and atomic fluorescence spectrometry) is of use across the span of reactive adhesive technologies. For example, the cure of anaerobic adhesives on non-reactive surfaces is usually assisted by the use of an active metal-based primer. Similarly, the cross-linking of silicone adhesives is promoted by the use of organometallic salts of cobalt, tin, iron, lead, and platinum. In the case of polyurethane adhesives, the key condensation reactions are catalyzed by tin salts (e.g., dibutyl tin dilaurate and stannous octoate).

The adhesive or primer is usually dissolved in an appropriate solvent and analyzed. A calibration curve is generated using standard solutions of the metals prepared in the same solvent and covering the anticipated concentration range. Where the matrix is difficult to solubilize or where very low levels (low ppm to ppb) are involved, the sample should be ashed prior to analysis. A low level of a binder component, e.g., *p*-toluenesulfonic acid should be added to the sample prior to heating to prevent loss of the metal through volatilization. The residue obtained following the ashing process is dissolved in a dilute mineral acid and analyzed by atomic spectroscopy. Where matrix interference is suspected, a standard addition approach may be used.

Packaging plastics may also be prepared for trace metals analysis by dry ashing prior to atomic spectroscopic analysis.

For matrices containing a high level of inorganic fillers, microwave-assisted acid digestion in the presence of concentrated mineral acids may be

required to facilitate the analysis of the sample by atomic spectroscopy.

Where the formulations embody significant levels of silicon dioxide or titanium dioxide the sequential use of nitric acid followed by hydrofluoric acid may be necessary to dissolve these oxides prior to analysis.

### Polarography

Where specification of the metal is considered to be important, polarographic analysis may be utilized. In the case of primers based on oil-soluble iron salts for use with anaerobic adhesives, the  $\text{Fe}^{2+}/\text{Fe}^{3+}$  ratio may be determined by differential pulse polarography in a supporting electrolyte based on ammonium pyrophosphate buffer adjusted to pH 9.0. The iron(II) form is known to be significantly more effective than the iron(III) form in the redox-based curing process.

Polarographic analysis may also be used to determine the level of selected chelating agents incorporated in an adhesive formulation. In the case of EDTA-based chelators, a standard addition approach using copper(II) is preferred. The supporting electrolyte is ammonium acetate at pH 5.0. This approach takes advantage of the fact that metal-chelate are typically reduced at more negative potentials than the metals themselves.

In passing it should be noted that voltammetric analysis is also very useful for determining many of the typical cure components used in the engineering adhesives. Thus, organic peroxides, aromatic amines, substituted hydrazines, thiols, etc., may also be determined at the mercury electrode.

### Other Adhesives Technologies

**Instant (cyanoacrylate) adhesives** The use of ‘instant adhesives’ based on  $\alpha$ -cyanoacrylate esters (**Scheme 8**) in both the industrial and consumer markets continues to increase. Typically, the methyl, ethyl, and butyl esters are used, but interest is also developing in the new ‘low-odor’ types based on alkoxyalkyl esters. The primary mechanism of polymerization is anionic. Weak bases including water can initiate polymerization to yield very high molecular mass homopolymers. Key additives are selected anionic stabilizers including both Lewis and protonic acids. Other additives may include organic polymers (e.g., poly(methyl methacrylate) functioning as thickening agents) and silica-based thixotropic agents.

**Scheme 8**

The nature of the ester may readily be confirmed by NMR ( $^1\text{H}/^{13}\text{C}$ ) and IR analysis. Protonic acid stabilizers typically present at the low mg per kg level may be quantified by nonaqueous titrimetry. Lewis acid stabilizers may be determined by an indirect approach such as atomic spectroscopy (emission/absorption).

The nature and concentration of the thickener may be determined using the following approach. The cyanoacrylate (CA) sample is initially diluted (1:1) with chloroform. Hexane is then added dropwise to the CA solution, with constant stirring. The thickening agent of high relative molecular mass will normally precipitate from solution as a white coagulated mass. The supernatant liquid (containing CA monomer) is decanted, and chloroform is added to the crude thickener to redissolve it. Dropwise addition of hexane is repeated, to effect slow precipitation of the thickener component. Further dissolution/precipitation of the solid, followed by a final hexane wash, yields a relatively pure sample of the thickening agent. The isolated polymer may then be characterized by IR, NMR, GPC, pyrolysis GC-MS, etc.

Although the preferred route of polymerization is anionic, free-radical polymerization is also possible, particularly at higher temperatures. Thus, low levels of suitable inhibitors, e.g., hydroquinone, *p*-methoxyphenol, 2,6-di-*t*-butyl-4-methylphenol, etc., may also be incorporated in the adhesive formulation. The type and concentration of such stabilizers may be determined by RPLC with UV detection.

Gas chromatographic analysis of cyanoacrylate esters is complicated by their highly reactive nature. The problems posed by premature polymerization were previously addressed by first reacting the cyanoacrylate ester to form the Diels-Alder adduct with an appropriate diene, e.g., isoprene. The resulting Diels-Alder complex was then analyzed by GC.

Problems presented by this approach included the presence of impurities contributed by the diene, etc. The approach currently used in our laboratory involves direct GC/flame ionization detector (FID) analysis on medium- or wide-bore cyanopropyl/phenyl/methyl silicone bonded-phase columns. The key prerequisite is to stabilize the sample against anionic polymerization by prior addition of a low level of an appropriate protonic acid stabilizer.

### Polyurethane Adhesives

A typical polyurethane sealant formulation may contain a urethane prepolymer, an isocyanate, plasticizer, fillers (including carbon black), and several other components. An important criterion is the concentration of residual isocyanate functionality available for further reaction. This may be established by reaction with

di-*n*-butylamine and back-titration of the unreacted amine with standardized hydrochloric acid. The identification of the base isocyanate may be determined by NMR ( $^1\text{H}/^{13}\text{C}$ ) spectrometry and/or pyrolysis GC. Identification of the plasticizer can be achieved if this component is isolated from the sealant matrix. A small quantity of sealant is allowed to moisture-cure (exposure to atmosphere for 24 h). The black, rubbery solid is then divided into small pieces with a knife, and extracted with 5 ml of hexane. The hexane solution is dried with a suitable drying agent (e.g., anhydrous sodium sulfate) and filtered to remove any solid particles. The solvent is removed from the sample by evaporation prior to analysis by, e.g., IR or NMR spectrometry.

The procedure yields a relatively pure extract of the plasticizer component, since the other major components in the polyurethane formulation are either physically or chemically immobilized in the cured polymer matrix.

### Epoxy Adhesives

The base resin in epoxy adhesive products can be readily identified by IR and NMR spectrometry. The most commonly employed resin in these products (both one-part and two-part) is that based on the diglycidyl ether of bisphenol A (bisphenol A epoxy resin). Other resins of importance include the cycloaliphatic epoxies and phenolic epoxy novolaks.

Epoxy products may contain high loadings of inorganic fillers (e.g., silica, talc, calcium carbonate). These can be removed by centrifugation of a sample that has been dissolved in a suitable solvent (e.g., acetone), prior to spectrometric analysis of the epoxy resin. The fillers may be analysed separately by IR spectrometry.

Hardener components in two-part products can also be analysed by IR/NMR spectrometry, provided fillers, pigments, etc., have been removed from the bulk sample.

Common curing agents in such products include anhydrides (e.g., phthalic anhydride, hexahydrophthalic anhydride, pyromellitic dianhydride), and also polyamine and polyamide-based hardeners.

One-part, heat-curing epoxies require no mixing, since polymerization is initiated by heating the product to trigger the curative in the formulation. Dicyandiamide is a high-temperature curing agent that may be detected in an epoxy matrix by either IR or LC analysis, the latter being carried out on an aqueous methanolic extract of the sample.

Thermal analysis (DSC) of heat-curing epoxides (Figure 6), such as specialist chipbonding products for the electronics industry, yields additional information about these materials, including heat of polymerization, peak temperature, onset of heat cure, and polymer conversion data.

The electronics industry has a particular concern regarding the level of 'ionics', such as the halides, which can contribute to metallization corrosion. Following defined extraction protocols involving the use of de-ionized water the extracts of both cured and noncured formulations may be analyzed by ion chromatography (anion and cation) with conductivity as the favored detection mode. Low  $\mu\text{g ml}^{-1}$  levels of extractable ions may be measured using this approach.

Where total halide, e.g., chlorine, is required then total combustion in a high-pressure oxygen bomb should precede the anion ion chromatography analysis.

### Cured Adhesives

In the case of a fully cured adhesive the analytical options are considerably narrowed. Should the curing reaction involve any significant degree of cross-linking, a relatively insoluble matrix will result. Appropriate analytical techniques under these circumstances would include IR (reflective techniques such as specular and diffuse reflectance), pyrolysis GC/MS, and photoelectron

spectroscopy. A computer-assisted search against appropriate library collections is a useful asset, particularly in the case of the first two techniques.

### Introduction

For many years, man has been concerned with the composition of the air, particularly when anthropogenic activities perturb air quality leading to detrimental health effects. In modern times there has been considerable effort to study the atmospheric processes which occur following emission of these

pollutants. Perhaps the most straightforward method of measuring the components in air is to ‘capture’ a sample and return it to the laboratory for analysis. More complex instruments are also available for deployment to provide on-site measurements.

In the field of air-quality standards, particulate matter (PM) has been divided into a number of size ranges; these are based on their health effects. PM10 are the largest particles (<10 μm) and PM2.5 and PM1.0 getting smaller, as the size of these particles decreases their ability to penetrate deeper into the body results in a serious escalation in their toxicity. Often it is not primarily the particles that are harmful but the organic materials that are often absorbed onto the particle surface, particularly when the particle is carbonaceous in character.

Sampling techniques vary according to the media to be monitored, e.g., gases or aerosols (aerosols are particles and/or droplets suspended in a bulk gas). Aerosols pose the more challenging to determine since there are significant difficulties to be overcome to ensure quantitative sampling of the full range of size fractions. The range of particle size and corresponding methods of sampling are given in Table 1.

Primary Considerations

Sampling of the atmosphere involves making decisions about the following:

- 1. Volume of the sample, variable from 1 ml to several m<sup>3</sup>.
- 2. Rate of sampling, variable from milliliters per minute to liters per minute.
- 3. Duration of sampling, jointly determined by the volume and the rate.
- 4. Collection limitations, specific for the target species under study.

Table 1 Methods of air sampling

Type of sample	Particle size range (μm)	Method
Particulates and aerosols	> 10	Gravitation
	> 5	Centrifugal
	> 1.0	Filtration
	100–1.0	Impaction
	80–0.2	Electrostatic precipitation
	10–0.1	Thermal precipitation
Gaseous	–	Adsorption
	–	Absorption
	–	Grab/whole air

As a general rule, collection efficiency above 80% is considered desirable.

The sampling technique should avoid any modification (physical or chemical) of the collected sample, by way of coalescence or chemical and/or physical destruction. Additional care should be taken to ensure preservation of thermal or photolytically labile species. Similarly, it is necessary to prevent errors caused by factors related to transportation, storage, and time-lag between collection and analysis. Collected samples must be stored in containers made from a suitably inert material such as glass or stainless steel. Plastic containers should not be used for samples containing oil or grease, phosphorus, dissolved oxygen, or organic compounds are to be analyzed. Glass containers should be avoided if silica or fluoro compounds are to be analyzed. It is preferable to follow accepted protocols for sample storage and transportation (e.g., US EPA-TO17).

Sampling Methods and Equipment

Sampling methods are of two types – (1) ambient sampling and (2) at-source sampling – which in turn can be further subdivided into continuous sampling and sequential sampling. Various instruments have been developed, based on the needs of these four types. Ambient air sampling is done at locations exposed to the atmosphere, whereas at-source sampling is carried out at the point of discharge before pollutants are diluted in the atmosphere.

Depending upon the objectives of the analysis, the choice of static sampling sites may vary from a busy street at a height of 0.5 m to a free-floating balloon at an altitude of several hundred meters. It is common to locate the sampling apparatus at a height of 2 m above ground, and it is essential that there are no obstructions, although there are no standard practices. Sampling sites that are accessible but are secure from tampering and have a reliable power supply for the equipment are favored by analysts. During the act of sampling, the sample intake should not be exposed to contamination from specific localized sources. Sites for stack sampling, for example, need to be selected keeping in view the safety of the analyst, easy access to the stack interior, satisfactory flow distribution, and convenience in adjusting the equipment. Generally, a location in a vertical flue (stack) sited eight flue equivalent diameters upstream from a flow disturbance caused by a bend, inlet, or outlet is considered ideal. For a rectangular cross-section, sample points are located at the centroids of smaller equal-area rectangles, and for a circular cross-section at the centroids of equal-area circular segments.

The source sampling can be carried out either when the source is stationary or when it is mobile. Stationary sources are of four types: (1) steady and uniform, (2) steady but not uniform, (3) unsteady but uniform, and (4) unsteady and nonuniform. The first type requires only one sample; the second requires composite sampling at several location; the third demands one sample spread over the entire operation; and the last type calls for a composite and repeated sampling.

Sampling of exhaust emissions from mobile vehicular and aircraft sources is conditioned by the mode of operation of the engine; and exhaust emission tests are usually performed by operating the vehicle on a dynamometer. For vehicular emission sample acquisition generally two types of engine dynamometers and one chassis dynamometer are used. Engine dynamometers generally used are either electric or eddy current absorption dynamometers. Other types such as water brake and fan brake dynamometers are not satisfactory and hence not commonly used. For stationary sources high-volume samplers can be used for sample collection.

The four components that form a sampling system (train) are the inlet/transmission, collection, flow measurement, and pump/air-moving. This allows the 'cleanest' route for the air avoiding as many potential sources of contamination/modification. Where the air is being analyzed at the sampling location, the analytical system is ideally placed between the collection and flow measurement sections. Exceptions to this are the collection of air by grab sampling and the collection of pressurized air samples using a clean bellows pump that is placed upstream of the sample canister.

### The Inlet/Transmission Components

The intake device may range from a thin-walled probe to a free vertical tube. Modifications are necessitated by the difficulties caused by adhesion of aerosols to the tube walls, condensation of volatile components within transfer tubes, or reaction of gaseous components with the material of the transfer tube and with the collected particles.

**Flow-measurement components** There are two types of flow-measurement components used in air sampling: volume meters and rate meters. Volume meters, which are of the dry gas meter, wet gas meter, or cycloid type, have an advantage as frequent checks are required in the use of rate meters to ensure accurate volumes. The advantage of rate meters is their compact size. They can be of several types, ranging

from venturimeters, orifices, nozzles, rotameters, pitot tubes, or turbines to hot-wire anemometers.

**Pumps/air-moving components** The air-moving component of the sampling system draws the sample through the system by creating a vacuum using a mechanical blower, aspirator, or hand-operated pump. Mechanical blowers are used for continuous flow at medium to high rates. Electrically powered pumps are preferable for avoiding contamination, likely to be caused by petrol-driven pumps. Another type of air-moving device is based on the principle of the centrifugal action of an impeller. In addition to these, liquid displacement vessels, evacuated containers, automobile intake manifolds, and expanding plastic bags and syringes are used for gaseous sample collection. In some applications air is pumped into the sampling system: this results in a positive pressure within the sample train, and any leaks are outward. This is particularly important in trace level sampling. In some applications air is pumped into the sampling system; this results in a positive pressure within the sample train and any leaks are outward, thus avoiding any possible contamination. This is particularly important when sampling at trace levels.

**Collectors** The components of sampling systems used for collection of aerosols and gaseous materials differ from each other.

*Collection components for aerosols and particulates* Isokinetic sampling is desirable in the case of aerosols. Researchers have studied errors occurring in anisokinetic sampling and have developed formulae for correcting the results. Anisokinetic sampling may lead to an inaccurate particle size distribution. When the sampled particles are smaller than 3–5  $\mu\text{m}$  in diameter, the requirements for isokinetic sampling can be relaxed. Isokinetic sampling is not required for stagnant and low-velocity masses. The flow rates involved, irrespective of iso- and anisokinetic sampling, vary between  $0.5 \text{ l min}^{-1}$  and  $750 \text{ l min}^{-1}$ . Difficulties in the sampling of aerosols arise from electrostatic attraction of particles toward non-conducting glass and plastic tubing, as well as the evaporation and hygroscopic nature of liquid aerosols or their reaction with solid particles. The following types of collection device are commonly used for the collection of aerosols and particulates.

**Filtration** Air is filtered for collection of aerosols by drawing the air sample through glass fiber, cellulose, sintered glass, or membrane or granular filters. On accumulation of the aerosol the flow through the filter is restricted, and collection is influenced by

**Table 2** Collection characteristics of selected filters

Filter	Composition	Fibre/pore diameter ( $\mu\text{m}$ )	DOP <sup>a</sup> efficiency (%)
Whatman 41	Cellulose (fibre)	3–20	72
Nuclepore	Polycarbonate (capillary pore membrane)	0.8	90
Microsorban	Polystyrene (fibre)	0.7	99.5
MSA1106B	Glass fibre	0.1–4	99.93
Millipore AA	Cellulose ester (membrane)	0.8	99.98

<sup>a</sup>Based on retention of dioctyl phthalate particles, 0.3  $\mu\text{m}$  diameter, at a face velocity of 0.27  $\text{m s}^{-1}$ .

electrostatic forces. The appropriate collection technique is determined by the nature of the filter, its collection efficiency, the pressure drop developed, the background concentration of trace constituents within the filter, and the structural supports used for the filters. Table 2 gives the types of commonly used filters, their composition, and efficiency.

A sample train consisting of a number of filters of decreasing pore size can be used to obtain a rough size distribution of particles. It is imperative that the collection efficiencies of such systems are determined and routinely monitored.

**Impingement/Impaction** In this technique, the air flow is forced through a jet, which increases the velocity of the particles and the carrier gas and changes their direction abruptly. There are wet and dry impingers. In the standard impinger, an orifice having a bore of 2–3 mm is used, through which the tube discharges the sample onto a flat plate of 5–10 mm width. In the midjet impinger, which is generally wet, a 3  $\text{l min}^{-1}$  flow rate is maintained. The Greenburg–Smith impinger is used as a wet or dry impinger, and it operates using a high-velocity air jet of 30  $\text{l min}^{-1}$  that impinges on a glass plate immersed in water or alcohol. The particles are collected in the surrounding fluid. The collection efficiency of this technique is  $\sim 100\%$  for particles greater than 1  $\mu\text{m}$  in diameter.

The mechanism of dry cascade impactors involves a series of sequential jets and collection plates, with increasing jet velocities and decreasing gaps between the collecting plates and the jets, as shown in Figure 1.

**Precipitation** Precipitation of aerosols is achieved using thermal or electrostatic precipitators. Thermal precipitation is effected through a sharp temperature gradient by suspending a wire across a cylindrical collection chamber. This device is especially effective for collection of particles smaller than 5  $\mu\text{m}$ . The suspended particles migrate from a zone of high temperature to a low-temperature one. The thermal force is negligible for a less than 750  $^{\circ}\text{C cm}^{-1}$

**Figure 1** Schematic of typical cascade impactor. (Taken from Reeve R (2002) *Introduction to Environmental Analysis*. Wiley; © Wiley.)

temperature gradient. The flow rate used is 7–20  $\text{ml min}^{-1}$  and is useful in microscopic investigations.

In electrostatic precipitators a high potential difference of 12 kV DC or 20 kV AC is maintained across the plates of a capacitor. The ions produced collide with aerosol particles and charge them; the particles are then collected at the respective electrodes. The device is efficient for the collection of particles ranging from 0.2–80  $\mu\text{m}$  in size at flow rates up to 85  $\text{l min}^{-1}$ . However, it is unsuitable for use in explosive atmospheres.

**Gravitational and centrifugal collection** The Earth's gravitational force of attraction causes a particle to settle at a rate dependent on the fluid drag forces opposing gravity. The rate of settling of the mass is dependent on the momentum of the particle which, in turn, is governed by the size and the flow velocity; in general, those of <7  $\mu\text{m}$  diameter will remain suspended.

In a centrifugal collector the air stream moves in a cyclonic manner, resulting in a net centrifugal effect on the particle, causing it to move outward to the collection surface, from it drops into a dust collection

chamber. The denuded gas leaves through a pipe extending through the top to the center of the cyclone. The collection device is efficient for particles having a  $>5\mu\text{m}$  diameter size. However, for collection of smaller particles the efficiency of collection can be improved by increasing the inlet velocity. Both the methods are useful for preliminary separation of large-sized particles.

Naturally settling dust particles are collected using a dustfall canister with a protection guard called a bird's eye.

### Samplers in common use

**British suspended particulate sampler** In recent years the old British standard method has been superseded by European directives such as EN12341 'Air Quality – Field test procedure to demonstrate reference equivalence of sampling methods for the PM<sub>10</sub> fraction of particulate matter. The determination of smaller size fractions (PM<sub>2.5</sub>) is also covered by a further directive. The US EPA have similar standard reference methods for particulate material (USEPA 40 CFR part 50). An early method was to simply compare the color of a filter paper through which a volume of air was drawn to an incremental gray scale (16 shades from white to black); this was then converted into an integrated particle loading with reference to the size cut-off offered by the pore size of the filter used. This was known as the 'black smoke index' method.

**High volume sampler for suspended particulates** A high flow rate ( $10\text{--}15\text{ l s}^{-1}$ ) is used to draw air through a  $20\text{ cm} \times 25\text{ cm}$  quartz fibre filter; this results in a typical sample volume of the order of  $1000\text{ m}^3$ . This sampler is useful for particles  $<100\mu\text{m}$  diameter and requires a protection guard. **Figure 2** illustrates a simple schematic of a typical high volume sampler. It is common for such samplers to include an impactor inlet to provide access to a specific size fraction such as PM<sub>10</sub> or PM<sub>2.5</sub> which are both monitored under modern air-quality legislation. Glass filters are used for their gradual headloss buildup and nonhygroscopic characteristics. In order to obtain good quantitation, high volume samplers require regular calibration of the flow system. It is quite common for a polyurethane foam (PUF) plug to be inserted downstream of the filter in order to collect smaller particles and, to some extent, semivolatiles.

**Tape filter samplers** This is useful for taking a series of sequential samples for predetermined sampling periods. A common sampler consists of an intake nozzle, a sampling head to hold and seal the filter tape, spools to collect the filter tape, an interval timer

**Figure 2** Typical-high volume sampler.

and clock, a flow meter, and a vacuum blower. It is operated at a  $7\text{ l min}^{-1}$  rate with cellulose filter tape for sequential sampling periods of 1–4 h. This allows the collection of samples for the black smoke index.

**High-volume cascade impactors** This technique consists of a stack of five 30 cm-diameter plates, each with 300 jet orifices, mounted over a standard high-volume glass fiber filter. The collection medium is perforated sheets of aluminum foil or glass fiber mounted on aluminum plates. Particle size fractions greater than  $7\mu\text{m}$  and less than  $1.1\mu\text{m}$  are collected at a flow rate of  $0.56\text{ l min}^{-1}$ .

### Collection components for gases

**General precautions** Air contains gases and vapors in addition to particulates. The collection techniques for gases are different from those used for aerosols. Several basic techniques are used for collecting gases and vapors, but their usefulness depends on the specific conditions of the source. A knowledge of the composition and history of the sample can help in proper selection and modification of the sampling technique to be used.

Most of the general considerations for aerosol sampling are also applicable to gaseous sampling; and an additional consideration relates to the temperature and pressure of the material at the source. Among the important methods used for collection of gaseous materials are the adsorption, absorption, condensation grab, and cryogenic processes.

**Adsorption** This is a surface phenomenon. Under equilibrium conditions at constant temperature, the

volume of gas adsorbed on the collection phase is governed by the relative surface area. The Langmuir adsorption isotherm, which is based upon homogeneous surface characteristics or for more complex multilayer surfaces the Brunauer, Emmet, and Teller isotherm, provides the collection parameters. The rate of adsorption is approximately inversely proportional to the volatility of a gaseous mixture. The commonly used adsorbents are activated carbon, silica gel, alumina, and various chromatographic support phases. Ideally, the adsorbent should have a large surface area, an affinity for polar or nonpolar compounds, a high and predictable retention capacity, desirable desorption properties, and a relative selectivity for atmospheric gases in selective applications. On the other hand it should have no chemical reactivity with the gases to be collected and should not be prone to fracturing, crushing, and flaking.

The release of the collected analytes is achieved either by solvent extraction (e.g., carbon disulfide) or more commonly nowadays by thermal desorption. Since the adsorbent is effectively acting as a chromatographic column, there are breakthrough limits that must be adhered to. This is generally taken as 66% of the volume of sample after which the least retained (most volatile) begins to elute from the outlet of the adsorbent trap. Specifications for the use of adsorbent tubes for sampling of volatile organic compounds (VOCs) are given in US EPA Compendium Method TO17.

**Gas chromatographic phase adsorption** Conventional gas chromatographic support materials coated with a liquid phase and porous polymeric materials are used for adsorption of gaseous samples. This is a versatile and rapidly evolving technique and is used for a variety of gaseous samples: chromosorb 101 and 102 have been used successfully for collection of organic gases and hydrocarbons at sampling rates of  $20 \text{ min}^{-1}$ . In this process, desorption of the adsorbed

phase is achieved by shaking it with hexane or by similar solvent extractions.

Adsorbent tubes can also be used for passive/diffusive sampling. Airborne pollutants diffuse along a short tube at the end of which is the adsorbent material. The rate of diffusion along this tube is governed by Fick's law of diffusion. This is a low cost and effective method of long-term monitoring, where tubes are typically deployed for a week. Diffusion tubes also have benefits since they require no power and are simple to use. This method is not limited to VOCs, however as inorganic species such as ozone, nitrogen dioxide, and sulfur dioxide can also be monitored using diffusion tubes.

**Absorption** In absorption collection, gas molecules are dissolved in a liquid collecting phase. The efficiency of the process depends on the contact surface area and is achieved by transforming the air stream into small, finely dispersed bubbles with a relatively long duration of travel through the absorbent. Absorption, like adsorption, is efficient at lower temperatures for volatile components. Table 3 shows the efficiency of absorption for various gaseous components. The commonly used absorption devices are fritted glass scrubbers, impingers, packed columns, countercurrent scrubbers, and atomizing scrubbers. Over the years these devices have undergone a number of modifications. Other frit materials are plastics and ceramics. Glass tubing with small holes can also be used. The absorbers are designed to detain for the rising bubbles for longer durations. Impingers are less efficient and are of the type discussed earlier.

**Condensation** The condensation method (cryotrapping) faces the primary problem of condensation of water containing components of interest.

Sequential traps at progressively lower temperatures, with the first designed for water vapor, can overcome this difficulty. To avoid combustion hazards,

**Table 3** Absorption efficiencies for various media and gaseous samples

Chemical	Absorption efficiency		
	Absorbent in gas washing bottle	Gas washing bottle efficiency (%)	Stack concentration ( $\text{mg l}^{-1}$ )
Sulfuric acid <sup>a</sup>	Water	99.8	72
Hydrochloric acid	Water	100	47
Perchloric acid	Water	99.8	41
Acetic acid	Water	99.5	1065
Nitric acid	Water	100	182
Ammonia	Water	84.3	103
Chlorine	2% $\text{Na}_2\text{CO}_3$	77.0	103
Ethylenediamine	Water	99.6	211

<sup>a</sup>Although depends on the particle size of aerosol.

the process is carried out at liquid oxygen temperature ( $-183^{\circ}\text{C}$ ). Coolants are placed in wide-mouthed Dewar vessels, and double-walled collector flasks are immersed in them. Coolants used are mixtures of water, ice, salt, dry ice, liquid air, and liquid oxygen.

**Grab/whole-air sampling** There is a wide range of materials from which sampling vessels are made: from polymeric bags to glass and metal containers. Bags are filled either by air being pumped into them or they are placed in an airtight container and the air around them is removed by a pump; when the inlet of the bag is opened to the atmosphere, air is drawn into the bag. Rigid containers can be evacuated, and upon opening the inlet, air is sucked in. This is a useful method, as it requires no power. The canister may also be fitted with a fixed orifice to prolong the sampling time. Vessels with an inlet and outlet can have the sample flushed through and closing the taps seals the sample. A final method to fill canisters is to pump air into them using a clean bellows pump.

It must be remembered, however, that whole air samples by their nature contain all the constituents from the air and thus reactions may occur after sampling; in particular, ozone reacts readily with many atmospheric species. Care must be taken to avoid low temperatures during storage/transportation since less volatile components may condense onto the internal walls. Often when trace analysis is to be conducted, internal surfaces are passivated either by electropolishing or by application of an inert silica coating (e.g., Silcosteel<sup>®</sup>, Restek Corp., US) in order to reduce wall losses. Evacuated canisters can be stored in preparation for use in case of gas release from chemical/industrial facilities. Emergency response services have even equipped remote-control helicopters with single

grab sample canisters that can be flown into highly hazardous areas following gas leaks.

**Source sampling** For collection of gaseous air from mobile (vehicular) sources, an exhaust gas sampling system has been developed in the United States in which the entire exhaust cycle is sampled and diluted to prevent condensation.

Sample collection equipment (pumps, flow meters, etc.) are similar to those discussed for aerosol collection.

## Introduction

The general atmosphere comprises nitrogen (78%), oxygen (21%), and argon (1%). In addition to these

gases there are a number of other species present at trace levels. These species can be of natural and/or anthropogenic (manmade) origin and in recent years significant changes in the composition of the atmosphere have been occurring as a result of large-scale emissions of certain pollutants.

These emissions are giving rise to problems on a global scale, such as the enhanced greenhouse effect and depletion of ozone from the stratosphere. In addition, regional problems such as localized ozone creation and smog formation have also been

observed. Although the concentrations of various specific pollutants vary with both time and location, it is generally true that they are highest in urban and industrial areas, although there are exceptions. As an example, certain 'secondary' pollutants such as ozone ( $O_3$ ) that are derived chemically from primary pollutants such as nitrogen oxides ( $NO_x$ ) and volatile organic compounds take time to form within the atmosphere and thus tend to be most concentrated at an appreciable downwind distance from urban and industrial areas.

The need to develop reliable analytical methods to determine the levels of both gaseous and particulate pollutants has gathered considerable impetus in the last 20 years or so and reliable, specific, rapid-response techniques are now available for many pollutants. In order to review the available methodology for the analysis of the various priority pollutants, it is necessary to classify them according to the physical form in which they are generally present in the atmosphere. The two classes of pollutant form are gaseous pollutants and particulate species.

## Gases

While it is not practicable to describe methods for all trace gases, some of the more important analytes and methods have been selected.

### Nitrogen Oxides

Nitrogen oxide (NO) and nitrogen dioxide ( $NO_2$ ) are collectively known as nitrogen oxides ( $NO_x$ ). They are generally grouped together because most anthropogenic  $NO_2$  derives from emissions of NO and they interconvert readily within the atmosphere. Major anthropogenic sources are vehicular emissions and stationary combustion of fossil fuels. Of the two compounds,  $NO_2$  has been implicated in a variety of respiratory ailments in humans and is generally regarded as the more important of the two species.

There are several methods available for the analysis of  $NO_x$ . All chemical methods involve the oxidation of NO to  $NO_2$ , while the chemiluminescence method involves the thermal decomposition of  $NO_2$  to NO. Three methods that are widely used are the Christie arsenite procedure, the diffusion tube method, and chemiluminescence. The principles behind these methods will be described briefly.

The arsenite method involves bubbling the air sample through a mixture of sodium hydroxide and sodium arsenite solution to form a stable solution of sodium nitrite. The nitrite ion produced is then reacted with phosphoric acid, sulfanilamide, and N-1-(naphthyl) ethylenediamine dihydrochloride to form an azo dye.

The analysis method can be modified for NO analysis if, after the  $NO_2$  is first removed from the gas stream, the remaining NO is then oxidized to  $NO_2$  with solid chromic oxide. The  $NO_2$  is then determined with arsenite as described above. This method can suffer an interference with  $SO_2$  if it is not first converted to sulfate ion ( $SO_4^{2-}$ ) by hydrogen peroxide prior to analysis. The method is relatively simple and inexpensive and has a reported detection limit of  $\sim 2 \mu g m^{-3}$ .

The diffusion tube method, which is highly selective toward  $NO_2$  but not entirely free of interferences, involves the absorption of  $NO_2$  by triethanolamine (the  $NO_2$  is converted to the nitrite ion in the process) after the sample gas has diffused passively along the plastic tube. The nitrite ion is then determined colorimetrically using a modified Griess-Saltzman reagent. This is a relatively simple method that, despite being potentially subject to a number of interferences from species such as  $SO_2$ , has been shown to give fairly reliable measurements, although it is best regarded as semiquantitative. One disadvantage of the method is that long sampling periods (up to 2 weeks) may be required to achieve reasonable sensitivity.

The chemiluminescence method is accepted as the most reliable and precise method currently available for the analysis of oxides of nitrogen. The basis of the method is the reaction between atmospheric NO and  $O_3$  (generated within the instrument). This reaction generates light (chemiluminescence), which is detected by a photomultiplier and converted to a concentration by calibration of the instrument with standard gas mixtures. To determine the  $NO_2$  content of the air,  $NO_2$  must be converted by thermal decomposition to NO and the instrument then measures  $NO_x$ .  $NO_2$  is then determined by difference between the  $NO_x$  and NO channels.

There is some potential for interference in the  $NO_x$  channel (and hence in the  $NO_2$  measurement) from species such as nitric acid. Detection limits for most commercial instruments are of the order of  $1 \mu g m^{-3}$ , although higher-sensitivity instruments are available. In recent years, instruments capable of measuring NO and  $NO_2$  at background ( $ng m^{-3}$ ) levels have been developed, based upon the NO/ $O_3$  reaction and also the  $NO_2$ /luminol chemiluminescent reaction.

### Sulfur Dioxide

Sources of sulfur dioxide ( $SO_2$ ) include fossil fuel combustion and smelting of nonferrous ores. It has been implicated in various respiratory ailments in humans and is known to play a major role in the formation of acid rain through its conversion to sulfuric acid in the atmosphere. There are a number of

methods available for the analysis of gaseous SO<sub>2</sub>; some of these suffer from serious interferences. Several of the more widely used methods are described below.

The methods involving collection in hydrogen peroxide are relatively simple to carry out. The basis of these methods is to absorb SO<sub>2</sub> in a solution of dilute H<sub>2</sub>O<sub>2</sub>, which converts it to sulfuric acid. The atmospheric concentration of SO<sub>2</sub> is then determined indirectly either by determining the free acid (H<sup>+</sup> ion) concentration by conductivity or pH measurements or by titration (acidimetric methods), or, alternatively, by determining the sulfate concentration by reaction with color-forming reagent followed by spectrophotometric measurement (colorimetric method), or by ion chromatography. One major problem with the acidimetric procedure is that any gas that can give an acid in solution and any alkaline gaseous species that will neutralize the acid (i.e., NH<sub>3</sub>) will interfere. The colorimetric and ion-chromatographic methods are more specific. The limits of detection for both methods are  $\sim 5 \mu\text{g m}^{-3}$  for a 24 h sample under ideal conditions.

A better colorimetric procedure involves bubbling air containing SO<sub>2</sub> through a solution of potassium tetrachloromercurate. The stable dichlorosulfite-mercurate ion that is formed in this reaction is then reacted with formaldehyde and bleached pararosaniline to form the intensely colored (red-purple) species pararosaniline methylsulfonic acid. The pH of the final solution is adjusted to 1.6 by the addition of phosphoric acid to the color reagent and the concentration of SO<sub>2</sub> is determined by measuring the product colorimetrically at  $560 \pm 2 \text{ nm}$ . This method has the advantage of being quite specific and has a quoted detection limit of  $5 \mu\text{g m}^{-3}$  for a 1 h sample.

The widely used continuous instrumental method for determination of SO<sub>2</sub> is based upon gas-phase fluorescence. Pulsed ultraviolet (UV) light (214 nm) is used to irradiate the air sample, which flows continuously through an optical cell. The SO<sub>2</sub> re-emits fluorescent radiation at 340 nm that is detected by a photomultiplier tube (PM), with the signal obtained being converted to concentration. This method is almost specific with a detection limit of  $\sim 1 \mu\text{g m}^{-3}$  in commercially available analyzers.

A second physical method that has been used for analysis of SO<sub>2</sub> in air is flame photometry. The sample is burned in a hydrogen-rich flame with light emission from the S<sub>2</sub> species at 394 nm being detected by a PM tube. However, since this wavelength is characteristic of sulfur, any other sulfur-containing species can interfere, and this method has largely been superseded by the gas-phase fluorescence method described above.

Sulfur dioxide (also nitrogen oxides) can also be determined by the differential optical absorption

spectroscopy (DOAS) method. This will be described later in the section on remote sensing.

### Carbon Monoxide

Carbon monoxide (CO) is predominantly produced from vehicular emissions, although it can be emitted in smaller amounts from other processes that involve the combustion of organic material. Its effects on health are primarily from its ability to displace O<sub>2</sub> from hemoglobin, and give rise to both morbidity and mortality due to the body's deprivation of oxygen.

There are two methods that are predominantly used to analyze CO; these are based on infrared (IR) absorption and electrochemistry. The IR technique is based on the fact that CO will absorb light at  $4.67 \mu\text{m}$  ( $2165 \text{ cm}^{-1}$ ). The CO concentration is then determined from the extent of absorption of the sample. There are two types of analyzer design, known as nondispersive and gas filter correlation analyzers. Interferences from CO<sub>2</sub> and water vapor can be overcome by instrumental design and are generally not significant. Reported detection limits are  $<0.5 \text{ mg m}^{-3}$  for this technique. The electrochemical cell technique is based on the electrochemical detection of CO as it is oxidized to CO<sub>2</sub>. Interferences from other oxidizable gases can be minimized by the use of special inlet filters and the detection limits obtained are comparable to the IR technique described earlier.

### Other Gas-Phase Species

In addition to the three important species already described, many other gas-phase pollutants are also considered important. These include nitric acid (HNO<sub>3</sub>), nitrous oxide (N<sub>2</sub>O) – which is a known greenhouse gas – as well as secondary pollutants such as ozone and peroxyacetylnitrate (PAN). A method that has been used widely for the determination of nitric acid and other species such as nitrous acid (HONO) and SO<sub>2</sub> is the annular denuder, in which the sample air is drawn through an annular glass tube (or series of tubes) that have been coated internally with a compound designed to trap the analyte species. After sampling, the denuder is extracted and the extract is analyzed by ion chromatography or other relevant procedure. Thus, for example, gaseous acids (HNO<sub>3</sub>, HCl, HONO, etc.) are collected in sodium carbonate, and ammonia is collected in oxalic or phosphorous acid. Nitrous oxide analysis is generally achieved by gas chromatography (GC) with electron capture detection. Only physical methods are feasible owing to the inert nature of this species and the lack of any chemical reactions that can be used.

Ozone, an important secondary pollutant, can be analyzed by DOAS (see Remote Sensing) and also by chemiluminescence, where the sample air is mixed with ethylene in a special flow cell at atmospheric pressure. The two gases react to produce an emission in the region of 400–600 nm and the light produced is monitored with a PM tube; the concentration of  $O_3$  can then be determined from the signal intensity. Interferences are negligible and the observed detection limits are  $\sim 1$  ppb in commercial instruments. The preferred technique for ambient air is UV light absorption in a folded path cell at 254 nm. Detection limits are  $\sim 1$  ppb. There is a potential interference from other gases absorbing at this wavelength (e.g., aromatic hydrocarbons). This is overcome by cycling the instrument between two modes: in one the absorbance of air passing through an ozone scrubber is measured, while in the other mode the absorbance of unscrubbed air is determined. The difference is due to the absorption by ozone. Calibration is via the absorption coefficient for ozone, as standard atmospheres are difficult to generate repeatedly. PAN can be determined by several methods. One such uses GC separation followed by an electron-capture detector. There are no known interferences to this method and the detection limits are  $\sim 1 \mu\text{g m}^{-3}$ , or lower if the PAN is cryogenically preconcentrated. In an alternative procedure, after chromatographic separation, PAN is thermally converted to  $NO_2$  and determined by the chemiluminescent reaction of  $NO_2$  with luminol.

## Particulate Matter

Particulate pollutants are emitted from many sources. Additionally, particles are formed in the atmosphere by both chemical and physical conversions from natural and anthropogenic gaseous substances. Particulate pollutants cover a size range from  $<10$  nm to  $>100 \mu\text{m}$ . The major proportion of the aerosol below  $1 \mu\text{m}$  is generally man-made, including sulfates from  $SO_2$  oxidation and carbon from vehicle exhausts, for example. Particles of a greater size are frequently natural (e.g., soil-derived, marine aerosol) but this division cannot be regarded as absolute.

Particulate matter is collected (sampled) either from suspension in the air (usually by filtration) or by collection of depositing particles as they fall out of the atmosphere under gravity or by turbulent or diffusive deposition. In general, airborne particles collected by air filtration are  $10 \mu\text{m}$  or less in diameter, while particles greater than this size predominate in deposit gauge collectors. In this section, the analysis of several important pollutants

that are generally present in a particulate from in the air will be described, together with a brief description of the method used to collect them.

### Mass

Most developed countries have legislated limit values of the concentrations of the mass of particulate matter in the atmosphere. These regulations are generally framed in terms of particles within specific size ranges termed  $PM_{10}$  and  $PM_{2.5}$ . The former refers to the mass of particles sampled through an inlet with a 50% cut-off efficiency at  $10 \mu\text{m}$  aerodynamic diameter (i.e., effectively all particles smaller than  $10 \mu\text{m}$  diameter), while for  $PM_{2.5}$  the 50% cut point for the sampler inlet is at  $2.5 \mu\text{m}$ . Both the US and European (CEN) reference methods for measuring particle mass depend upon sampling a known volume of air through a high-efficiency filter that is weighed under controlled conditions of temperature and humidity before and after sampling. Continuously reading instruments include the  $\beta$ -absorption gauge (based on absorption of  $\beta$ -radiation by collected particles) and the tapered element oscillating microbalance. Because these instruments often precondition the air stream (e.g., by heating) before sampling, the measurements may differ from those made by the reference methods which do not permit such conditioning.

### Metals

Metal-containing particles are generally collected by drawing air through a filter and subsequently analyzing the filter on which the particles are trapped. The material used for the filter is dependent on the species that is to be collected. The choice of filter material is also related to the requirements of the subsequent analysis step (i.e., low blank content). Two important metals that have environmental significance are lead (Pb) and cadmium (Cd). There are several methods available for the analysis of these two species.

The most commonly used technique is atomic absorption spectroscopy (AAS). Lead- and cadmium-containing particles are collected on membrane filters (usually Teflon or cellulose ester), extracted into strong acid solution, and analyzed by AAS. If the procedures are optimized there are no interferences and detection limits are of the order of  $10 \text{ ng m}^{-3}$  for lead and  $1 \text{ ng m}^{-3}$  for cadmium in a 24 h sample. The figures given are for electrothermal atomization using a graphite furnace; atomization using a flame results in reduced sensitivity and consequently higher limits of detection. Multielement analysis of metals

dissolved from airborne particles is often achieved by use of inductively coupled plasma-optical emission spectroscopy, or if high sensitivity is required, inductively coupled plasma-mass spectrometry.

For X-ray fluorescence the samples are collected by filtration and placed in the X-ray spectrometer without sample pretreatment. When irradiated with X-rays, the metals re-emit secondary X-rays at wavelengths characteristic of the individual metals. There are little interferences and good limits of detection can be obtained.

### Organic Species

Methods for the analysis of particulate organic air pollutants are of necessity complex. The majority of methods require filter collection of the sample followed by extraction and a chromatographic separation. For example, in the analysis of polycyclic aromatic hydrocarbons (PAHs) the extraction and analysis procedure involves a Soxhlet (or other) solvent extraction off the glass fiber or Teflon filter used to collect the sample, followed by analysis of the extracted sample by liquid chromatography. The detectors are either UV absorption or fluorescence monitors. Alternatively, the extracts of PAHs may be analyzed using gas chromatography-mass spectrometry techniques. Detection limits in the picogram ( $10^{-12}$  g) range have been reported.

### Inorganic Ions

Inorganic particulate ions such as nitrate and sulfate, which are attracting considerable interest owing to the involvement of these species in acid rain studies, are generally collected using filters. The use of polytetrafluoroethylene (PTFE) membrane filters is generally recommended, especially for nitrates, owing to the low background of soluble nitrate ion in this paper. A number of colorimetric methods may be used for nitrate analysis, but ion chromatography is nowadays almost universally used. PTFE filters are also appropriate for sulfate collection. It has been shown that other media such as glass fiber are unsuitable for sulfates owing to artifact formation from  $\text{SO}_2$  reactions on the filter surface. The filter is extracted with a known quantity of aqueous sodium carbonate-sodium bicarbonate buffer containing 10% (v/v) isopropanol and either mechanically shaken or placed in an ultrasonic bath for 1–2 h to complete the removal of the analytes from the filter. The extracts are then analyzed by ion chromatography. Detection limits of well below  $1 \mu\text{g m}^{-3}$  for 3 h samples can readily be obtained using this procedure.

## Remote Sensing

The term 'remote sensing' is often associated with observations of the earth from orbiting satellites. However, in recent years the use of remote sensing instrumentation has been applied to the monitoring of air pollution in the atmosphere. The term itself refers to the fact that the instruments used to make measurements can do so not only at the site at which the instrument is located but also at points remote from it. Several types of instruments have been used for air pollution monitoring and some of the more important ones will be discussed briefly in this section.

### Single-Wavelength Lidar

The principle of lidar is that a laser pulse is fired into the atmosphere and as it proceeds along its path, radiation that is scattered by aerosol and other particles is directed back toward the laser where it is collected with a telescope and measured with a detector. The lidar system can be operated either in single- or multi-wavelength mode (by using a tuneable laser) so as to detect a number of different species according to the attenuation they cause at specific wavelengths. Several practical systems have been developed to monitor species such as  $\text{SO}_2$  and  $\text{O}_3$  but the instrumentation required is complex and very expensive. Analysis of the signal also requires considerable expertise.

### Differential Optical Absorption Spectroscopy

The DOAS technique originally developed by Platt, Perner, and co-workers uses a broadband light source with an emission in the wavelength region from 200 to  $\sim 700$  nm. This light, which is collimated by a parabolic mirror, passes through the outside air over a pathlength that can be up to 10 km before it is recaptured with a second parabolic mirror and focused to the detector using an optical fiber. By varying the wavelength of the light source the concentrations of specific species can be determined as the light beam is absorbed by trace species that can absorb light at that particular wavelength. The concentrations of these species can then be derived from Beer's law.

Several instruments have been developed to monitor air pollutants such as  $\text{SO}_2$ ,  $\text{NO}_2$ , HONO, and  $\text{O}_3$  and these are now commercially available. Although these once seemed likely to revolutionize air quality monitoring, their uptake in practice has been very limited. Most statutory air quality networks require point monitors, and long-path instruments are not accepted.

## Workplace Air

**J Yu and R M A Hahne**, University of Washington, Seattle, WA, USA

## Introduction

As a basis for the prevention and control of occupational hazards, workplace air analysis has undergone rapid development in the field of analytical science during the last two decades. It paralleled the establishment and development of occupational exposure guidelines for hazardous materials set by government/advisory agencies.

Workplace air analysis can be distinguished from other types of analysis: the selection of sampling medium, time, and location are crucial steps in workplace air analysis; transportation and storage of the samples may also influence the measurement results; and, almost always, real-time monitoring or quick turnaround analysis time is required. Several international organizations have issued guidelines and standards on methods for measuring air contaminants in the working environments, such as the World Health Organization, the International Union of Pure and Applied Chemistry, and the International Organization for Standardization. Most national government agencies/organizations, such as Occupational Safety and Health Administration (OSHA), USA; National Institute of Occupational Safety and Health (NIOSH), USA; The Commission of the European Union; and the Health and Safety

Executive (UK) have also established more specific standard methods for the sampling and measurement of airborne contaminants in workplace environments.

In this article, regulatory requirements for workplace air quality will be reviewed, as will general principles of workplace air analysis of both real-time experiments and those performed in the laboratory. Analytical methods for contaminants concentrated from air samples will be presented and discussed.

## Legislation

Although it has long since been recognized that workplace air contaminants can be hazardous to workers' health, a significant driving force for workplace air analysis is governmental regulations, apart from the nonregulatory guidelines and recommendations such as the threshold limit values (TLVs) of the American Conference of Governmental Industrial Hygienists (ACGIH), which specifies concentrations of airborne contaminants in the workplace air to which nearly all workers may be repeatedly exposed without adverse health effects. TLVs may be expressed as full-shift, time-weighted average (TWA) concentrations in the breathing zone of a worker (TLV-TWA), as short-duration concentrations (~15 min), or as 'instantaneous' ceiling concentrations that are not to exceed TLV-C at any time.

In the United States, permissible exposure limits (PELs) of the Occupational Safety and Health Administration (US Department of Labor) exist for over 400 different organic and inorganic materials.

In Canada, individual provinces have jurisdiction for the establishment and enforcement of workplace airborne contaminant levels in private industries, and most of the provinces have established their own occupational exposure levels.

In Germany, the MAK (Maximale Arbeitsplatz Konzentration – maximum workplace concentration) values established for workplace air have been adopted by the Ministry of Labor and are mandatory. MAKs are the maximum concentrations allowed for exposures of repeated or extended periods of time. There are currently ~150 MAK values; concentrations exceeding the MAKs are allowed for reduced durations or reduced frequencies. In addition, technical guidance concentrations (Technische Richtkonzentrationen) have been established for substances identified as carcinogens and potential carcinogens.

In the United Kingdom, there are two types of occupational exposure limits: occupational exposure standards (OESs) and maximum exposure limits (MELs). An OES is set at a level at which there is no indication of risk to health, while the MELs are set for materials for which serious health implications exist, but which due to socioeconomic factors must have a numerically higher value in order for the controls associated with certain uses to be regarded as reasonably practicable.

Many other countries have OELs with varying degrees of enforcements, updated annually.

Measurements of workplace air are frequently made to demonstrate compliance with legal or other standards, but may also be made for other purposes, including identifying unknown potential hazards, obtaining data for epidemiological (exposure-response) studies, and demonstrating the efficiency of control measures.

## General Principles

The type of air contaminants that occur in the workplace depends on the raw materials used and the processes involved. Air contaminants can be classified into two groups based on their physical properties: (1) aerosols (a suspension of liquid or solid particles in the air), and (2) gases/vapors.

The analysis of workplace airborne contaminants depends on the specificity, sensitivity, accuracy, reproducibility, and stability of the analytical methods, similar to that in other chemical and physical analyses.

As OELs continue to decline, the analytical method of choice must be sensitive enough to reliably quantitate the workplace air contaminant at or below the designated exposure level. As an example of potential problems associated with lack of sensitivity, when the ACGIH announced its recommended

change in the short-term exposure limit for formaldehyde in 1990, there was only a single device commercially available that had the sensitivity to measure formaldehyde at that concentration for such short durations.

The need for accuracy in a workplace monitoring method is vital, since the measurements need to reflect the actual conditions in the workplace. On the other hand, given the temporal and spatial variability in most airborne contaminant concentrations in the workplace, it is generally not required that the monitoring method be highly accurate, i.e. within a few percent of the 'true value'. The NIOSH (USA) recommends that (1) the overall bias of a monitoring method be <10% of the values determined by a well-characterized independent method, and (2) that the overall precision of sampling and analysis should be such that the total error is <25% in at least 95% of the samples analyzed, based on the analysis of 6–10 samples at each of three or four concentration levels.

The analytical methods employed for workplace air analysis can be categorized into two general categories:

1. Direct reading instruments for use in the field.
2. Sample collection with subsequent laboratory analysis.

The direct reading instrument can provide data on exposures in the field. There are several reasons why one chooses direct reading instruments:

1. Quick turnaround time; there is no need to wait for long, often costly, laboratory analyses.
2. Can identify high short-term exposure that may lead to acute effects, e.g., facilitate confined space entry, and also provide estimates of long-term exposures with correct sampling procedures.
3. Provide some alarm functions for evacuation or remedial action.

On the other hand, field sampling followed by laboratory analysis provides the kind of precision and accuracy that no field/onsite measurement can consistently provide.

## Aerosol (Particulate Matter)

Airborne particulates can be either solids or liquids. Dust, fumes, smoke, and fibers are dispersed solids; mists and fogs are dispersed liquids.

### Sample Collection

Particulate matter ranges in size from visible to microscopic. Particles can be sampled to determine the

total quantity, or only the respirable fraction. The respirable particles are those that are retained in the lung and are generally considered to be of an aerodynamic size below 10  $\mu\text{m}$ .

**Filters** For total particulate/aerosol sampling, the open- or close-faced 37 mm filter cassette is the most popular in many countries. A newer type of sampler for inhalable dust is the IOM sampler with a 25 mm filter. Many studies have shown that the IOM sampler provides the best reference for inhalable aerosol. Other samplers that are emerging for this purpose are Respicon, and the Button samplers. There are several types of filters commonly used for this purpose: glass fiber, mixed cellulose ester fiber (MCE), and poly(vinyl chloride) (PVC) filters. They are selected based on their ability to collect material and their suitability for laboratory analysis. For example, PVC filters are normally used for gravimetric analysis and MCEs are used when a chemical analysis is needed followed by digestion or extraction.

**Cyclones** A cyclone is used to collect particles of respirable size, which separates out the large particles from an air stream by the centrifugal motion of the airflow, with the remaining respirable particles being directed onto a collection device such as a filter. Several types of cyclones are commercially available: Dorr–Oliver cyclone, Higgins–Dewell, SKC Aluminum, and SKC GS.

**Multistage Impactors** Separation in this device is based on the momentum of particles of various masses. All the particulates in the air are collected, but are separated by size on a series of multiple stages. **Figure 1** shows four commercially available devices for the size separation and collection of airborne particulates.

**Figure 1** Four commercially available devices for the size separation and/or collection of airborne particulates. From left to right: IOM sampler, button sampler, cascade multistage impactor, cyclone.

## Physical Analysis

There are two common physical analyses that can be performed on the particulate matter collected on filters or other media.

Gravimetric analysis is the most commonly used physical method, in which the filter is weighed both pre- and postsampling using a microbalance. The quotient of the increase in filter weight divided by the air volume drawn through the filter yields the average concentration of the airborne particulate matter during the sampling period.

The second physical method of analysis for particulates is microscopy. Although there are a number of microscopic techniques used for the qualitative and quantitative analysis, the most common technique used for the analysis for workplace air is phase-contrast microscopy (PCM), used in the quantitation of fibers, especially asbestos trapped on a filter. Another type of microscopic method, electron microscopy, including scattering and transmission electron modes, has seen increased popularity due to its superior resolution and magnification power, despite the high cost and other disadvantages. In scanning electron microscopy (SEM), a very fine ‘probe’ of high-energy electrons scans across the surface of the specimen, inducing the emission of secondary electrons or reflection of the backscattered electrons from the primary beam. The intensity of emission of both secondary and backscattered electrons is very sensitive to the angle at which the electron beam strikes the surface, i.e., to topographical features on the specimen. The emitted electron current is collected, amplified, and displayed as a fluorescent image on a cathode ray tube.

## Chemical Analysis

In many cases, aerosol/particulate matter trapped on a filter paper is extracted from the filter using solvents or acids, after which the extract is analyzed. This technique is used for the analysis of: polynuclear aromatic hydrocarbons trapped on membrane filters or solid sorbents, various pesticides from polyurethane foam filters, many metals and their salts, and crystalline silica on PVC filter samples. The polynuclear aromatic compounds and pesticides can be analyzed using either gas chromatography (GC) or high-performance liquid chromatography (HPLC); the metals are analyzed using atomic absorption/emission spectrophotometry (AAS/AES, either flame or flameless, depending on the metal), inductively coupled plasma spectrometry, or ion chromatography. The analysis of crystalline silica is done using X-ray diffraction (XRD), infrared (IR), or visible spectrophotometry.

Ion chromatography can be used for the quantitation of a mixture of anions collected as salts, which might include such substances as fluoride or nitrate ion. Specific ion-selective electrode measurements are also used for the analysis of numerous anions and cations. Special attention should be given to elimination/minimization of interferences from the matrix.

In some cases, the filter is used as both particulate trapping medium and as a substrate for holding a derivatizing reagent that reacts with and stabilizes the particulate matter. For example, 1-(2-pyridyl)piperazine-coated glass fiber filters are used to trap and react with particulate methylene bisphenyl isocyanate to form a derivative that is then analyzed using HPLC coupled with a fluorescence detector.

The direct-on-filter technique for either XRD or IR, in which sampling and analysis is accomplished using the same filter, has been accepted widely as an alternative to the routine analysis following desorption. This is more efficient as it bypasses the intensive sample preparation; less contamination and less sample loss are also added advantages.

There are also other techniques that are used frequently to characterize particulate matter collected from workplace air, for example, X-ray fluorescence (XRF) analysis – both lab-based wavelength-dispersive and hand-held energy-dispersive XRF spectrometry – are used for identification and quantitation of either bulk samples or air filters for numerous chemical elements. The latter is now available with both tube-excitation and radionuclide-excitation sources.

### Direct Reading Aerosol Monitors

Several types of direct reading monitors are available for measuring airborne aerosol concentrations.

The most popular direct reading aerosol monitors are light-scattering devices, which operate by illuminating the sample as it passes through a chamber and measuring the scattered light at a certain angle. This type of monitor is sensitive to the size, shape, and refractive index of the particles. It is used for determining aerosol size and count.

Another type of aerosol monitoring device relies on the behavior of a piezoelectric crystal, whose oscillation frequency changes with the mass of aerosol deposited on it. It is called piezoelectric mass sensor. After each sampling period, the concentration of the aerosol is displayed and the crystal is automatically cleaned and ready for the next measurement. Sampling efficiency is affected by both the mass and the size of the particles. Very low sensitivity is observed when the particle size is larger than 10  $\mu\text{m}$  in diameter or larger masses of particles are collected.

## Gases/Vapors

A large number of gases and organic vapors occur in various workplaces, and many different techniques are required to assess them. Gas and vapor sample collection for monitoring is relatively simple compared to dust sampling. There is no size sampling requirement – monitoring simply requires that one collects and measures the concentration in the atmosphere. Exposure is based on the total amount available for inhalation.

### Sample Collection

Personal air sampling is preferred over area sampling for evaluating worker exposure to contaminants in workplace air. The worker wears a sampling device that is placed very close to the breathing zone to collect an air sample. Area air samples are normally used to evaluate background concentrations and locate sources of exposures. The sampling device is placed in a fixed location in the area of interest.

**Active sampling/sorbent tubes** Probably the most common and versatile type of sample collection device is the solid sorbent tube. These small cylindrical tubes, 3–8 mm internal diameter, containing tens to thousands of milligrams of one or a combination of sorbents, have the workplace air drawn through them to facilitate trapping the contaminant(s) of interest. Solid sorbents commonly used are various forms of activated charcoal or carbon for stable compounds; silica gel for collecting polar compounds such as alcohols, amines, and phenols; synthetic polymers such as various chromsorb, ambersorb, XAD, and Tenax for a wide range of low level of higher molecular weight organics compounds.

Active sampling requires a sampling pump to draw air through the sorbent tubes. The sampling pump needs to be calibrated (with the entire sampling train assembled as it will be used in the field) to within  $\pm 5\%$  of the recommended flow rate according to OSHA analytical methods.

**Passive monitors** Passive monitors provide personal sampling without the use of sampling pumps. They rely on the movement of contaminant molecules across a concentration gradient, which for steady-state conditions can be defined by Fick's first law of diffusion. In simple terms, contaminants move from an area of high to low concentration at defined rates.

Common types of passive monitor involve the trapping of the air contaminant of interest using a solid sorbent or a reactive material contained behind

**Table 1** Passive monitors for occupational air sampling

<i>Sampler model</i>	<i>Manufacture</i>	<i>Target contaminants</i>	<i>Sampling media</i>	<i>Analytical method</i>
3M 3551	3M	Ethylene oxide	Hydrogen bromide treated charcoal disk	GC-ECD
3M 3721	3M	Formaldehyde	Bisulfite-impregnated paper	Visible spectrometry
GMD 570	GMD	Formaldehyde	Glass fiber filter impregnated with 2,4-DNPH	HPLC-UV
526-200/201	SKC	Formaldehyde	Bisulfite-impregnated paper	Visible spectrometry
AT571	Assay technologies	Formaldehyde	Glass fiber filter impregnated with 2,4-DNPH	HPLC-UV
575-Series	SKC	VOCs	Charcoal/Anasorb 747/727	GC-FID
SKC 520	SKC	Inorganic mercury	Anasorb C300	AA
NITROX	Landauer	Nitrous oxide	Molecular sieve	IR
3M3500	3M	VOC	Charcoal	GC-FID, GC-MS

a diffusive barrier. After use, the sorbent is removed and desorbed with a solvent and then analyzed. Another type of passive monitors involves the diffusion of the gas or vapor along an open path into a solution or onto a treated sorbent with which the contaminant reacts. **Table 1** lists manufacturer and model details for both types of passive monitors.

Passive monitors are relatively inexpensive and easy to use, and most commercially available monitors meet or exceed NIOSH accuracy requirements.

**Grab samplers** Grab samples are collected to measure gas and vapor concentrations at certain time and place, which can be used to evaluate 'peak' or ceiling exposures. Grab samples are collected mostly in the following situations: onsite analysis for certain field applications; emergency situations, like spills, leaks, when instantaneous sampling and analysis is critical; or when other sampling media/methods are not available.

Flexible sampling bags made of different materials or evacuated rigid containers, such as SUMMA canisters, are used for grab sample collection.

### Laboratory Analysis

The analysis of material trapped on solid sorbents is done in a number of ways. Arguably the most common analytical technique is desorption in a suitable solvent with gas chromatographic analysis of the resulting solution. There has also been a considerable body of work done on thermal desorption of the trapped material, with or without preconcentration of the desorbed material prior to gas chromatographic analysis. Thermal desorption introduces the potential for pyrolysis of the material of interest, and thus its use is somewhat limited, in comparison to solvent desorption. Mass-selective (MS) detectors and the flame-ionization detectors (FIDs) are the most commonly used detectors for this purpose. Both detectors are considered to be universal detectors for organic compounds; the FID is used mostly for

quantitation while MS can be used for both qualitative identification and quantitative analysis. Other detectors such electron-capture, thermal conductivity, Hall electrolytic conductivity, nitrogen-phosphorus, and alkali flame ionization detectors have all been used for the analysis of workplace air contaminants.

While the gas chromatographic technique is used for most of the analysis of volatile and semivolatile contaminants in workplace air for compounds with relative low volatility, or compounds that are derivatized for better stability or increased sensitivity, HPLC is the analytical method of choice. UV – visible and fluorescence detectors are the two common types of detectors that are used.

Other analytical methods used for the analysis of solid sorbent samples include ion chromatography, ion-selective electrodes, and polarography measurements.

**Table 2** lists the common analytical methods discussed with their respective detection limits and dynamic range.

### Direct Reading Analysis

Direct reading instruments are one of the most important tools that are available to occupational hygienists to detect and quantify workplace air contaminants. These instruments allow real-time or near real-time measurements in the field, thus eliminating the lag-time if the samples have to be sent for laboratory analysis.

**Electrochemical sensors** Electrochemical sensors are widely used for the detection of toxic gases at the parts per million (ppm) level and for oxygen in levels of percent of volume (% vol). Toxic gas sensors are available for a wide range of gases, including carbon monoxide, hydrogen sulfide, sulfur dioxide, nitrogen dioxide, chlorine, and many others.

Although the sensors are designed to be specific to each gas, there are often some cross-interferences with

**Table 2** List of analytical methods for gas/vapor analysis

<i>Analytical method</i>	<i>Typical analytes</i>	<i>Typical detection limit</i>	<i>Linear dynamic range</i>
GC-FID	Hydrocarbons	10–100 pg	10 <sup>7</sup>
GC-ECD	Organohalogens, chlorinated solvents, and pesticides	0.05–1 pg	10 <sup>4</sup>
GC-FPD	Sulfur and phosphorus compounds	10–100 pg	10 <sup>3</sup> –10 <sup>4</sup>
GC-NPD	Organonitrogen and organophosphorus compounds	0.1–10 pg	10 <sup>3</sup>
GC-PID	Compounds ionized by UV	2 pg C per s	10 <sup>7</sup>
GC-MS	Tunable for any compound	10 pg–10 ng (depending on SIM or scan)	10 <sup>5</sup>
GC-AED	Tunable for any compound	0.1–20 pg s <sup>-1</sup>	10 <sup>3</sup> –10 <sup>4</sup>
HPLC-UV	Conjugated organic compounds	0.1–1.0 ng	10 <sup>4</sup> –10 <sup>5</sup>
HPLC-fluorescence	Highly conjugated compounds like PAHs, isocyanate derivatives, etc.	1–10 pg	10 <sup>3</sup> –10 <sup>4</sup>
Ion chromatograph	Anions	0.1–1.0 ng	10 <sup>3</sup> –10 <sup>4</sup>

other gases present. Overall, electrochemical sensors offer very good performance for the routine monitoring of toxic gases and percent of volume oxygen present in both portable and fixed gas monitors.

**Combustible gas instruments (CGIs)** Three types of CGIs are available. The first is the catalytic sensor, which is commonly used to detect and quantify combustible gases and vapors from 0% to 100% LEL (lower explosive limit). The sensor consists of two elements: detector and reference. Both elements consist of metal coils operating in a Wheatstone bridge circuit. The burning gas increases the detector's temperature, resulting in an increase in resistance in the element. The sensor's response to a combustible gas depends on the chemical composition, the molecular weight, and vapor pressure of the gas.

The catalytic sensor is less sensitive to temperature and humidity effects, offers repeatable performance, and is relatively stable. However, it is susceptible to poisoning or inhibition from some gases, which may decrease its sensitivity or damage the sensor beyond recovery.

The second type is the thermal conductivity sensor, which has been used in instruments for measuring combustible gases above the % LEL range and for leak detection for many years. Like the catalytic sensor, this one also consists of two wire elements of detector and reference. The response depends on the thermal conductivity of the gas being detected. Some advantages of the thermal conductivity sensor are that it does not require oxygen to operate and is not susceptible to poisons. One drawback is that it cannot measure gases with thermal conductivities similar to the reference gas (nitrogen). Thermal conductivity sensors are used primarily in portable gas leak detectors.

The third type is the metal oxide sensor, which is described in more detail later in this article.

**Photoionization/flame-ionization detectors (PIDs/FIDs)** PIDs and FIDs detectors are often used in situations where high sensitivity (sub-ppm levels) and limited selectivity (broad-range coverage) are desired. The normal working range is between 0.1 and 100 000 ppm for FID and 0.2–2000 ppm for PID. PID/FIDs are commonly used for detecting volatile organic compounds (VOCs) such as benzene/toluene/xylene, vinyl chloride, and hexane, and provide quick response for this growing concern.

A PID operates by ionizing components of a sample stream with high-energy ultraviolet UV light (while FID operates by ionizing components with high-temperature hydrogen/air flame) and detecting the resulting charged particles collected at an electrode within the detector. Advantages of this technology include the fast response time and excellent shelf-life. PIDs suffer from sensor drift and humidity effects; therefore, calibration requirements are more demanding than other common gas detectors.

**IR gas analyzer (nondispersive IR (NDIR) absorption)** The NDIR sensor, commonly referred to as the IR sensor, is based on the principle that many gases absorb light energy at a specific wavelength, typically in the IR range.

The limitation of NDIR technology for gas detection depends on the uniqueness of the absorption spectrum of a particular gas. IR sensors can detect gases in inert atmospheres (little or no oxygen present), are not susceptible to poisons, and can be made very specific to a particular target gas.

NDIR sensors are also extremely stable, quick to respond to gas, can tolerate long calibration intervals, and have a wide working range (sub-ppm to

low percentage level). IR sensors are commonly used to detect methane, carbon dioxide, and nitric oxides in both portable and fixed gas detection instrumentation.

**Photoacoustic sensors (PAS)** Quantification of air contaminants by PAS involves the use of UV or IR radiation to quantify air contaminants. It involves the absorption of a pulse of light energy by a molecule and the subsequent detection of a pressure wave generated by heat energy released by the molecule upon its return to the ground state. Photoacoustic spectroscopy analysis is nondestructive, can be done in real time, and can be a few orders of magnitude more sensitive than conventional UV-vis spectroscopy. Detection limits are chemical-specific and are reported to be between 0.001 and 1 ppm.

**Fiber optic sensors** The use of fiber optic technology is relatively new and fiber optic sensors are relatively inexpensive to manufacture.

One proven method of optical sensing uses a fiber coated with chemical reagents. A beam of light is guided over the fiber probe as the analyte gas is introduced. The sensor detects the luminescence changes resulting from the reaction of the chemicals with the gas. This type of optical sensor can be formulated for a variety of gases such as oxygen, ammonia, chlorine, and hydrogen, where the chemical principles are well known and suitable laser and light emitting diodes sources are available.

**Solid-state sensors** Solid-state sensors, also referred to as metal oxide sensors, are best used as general survey instruments because of their lack of selectivity/specificity. This type of sensor has a rather narrow working range of 1–50 ppm. A variety of MOS sensors are available for the detection of combustible gases, chlorinated solvents, and some toxic gases, such as carbon monoxide and hydrogen sulfide.

During operation, the sensing element is heated to 250–350°C. When gas enters the sensor, it reacts with the oxide coating, causing a decrease in resistance between the two electrodes, which is then measured.

**Portable GCs** GC and GC-MS remain dominant techniques for the determination of multiple volatile and semivolatile organic compounds in workplace air analysis. Portable gas chromatographs were introduced in the late 1970s and the technology has continued to evolve ever since. Most field GCs consist of an injection system with either syringe

**Figure 2** Photovac Voyager portable GC.

mode or loop mode, capillary or packed columns, a programmable oven, and one or more detectors. Most common detectors used in portable GCs are FID, PID, or ECD (electron capture detector). A field GC can be as accurate as  $\pm 5\%$  of the reading and it also offers a wide dynamic range, from very low-ppb to hundreds of ppm concentration levels for FID/PID.

The Photovac Voyager, a fifth-generation portable GC, is shown in **Figure 2**. Features of the Photovac Voyager include a three-column system and dual PID-ECD detectors. The Voyager also includes a factory-programmed assay that provides preset instrument operating parameters and compound library to simplify operation.

Sixth-generation portable GCs, which are high-speed portable gas chromatographs, have been introduced recently. They can analyze single or multiple compounds within as little as a few seconds up to a couple of minutes.

**Non-instrumental methods/detector tubes** Chemical indicator tubes, using noninstrumental technology, are widely used for the analysis of workplace air in a real-time basis. Sealed glass tubes are filled with a reagent specifically sensitive to a

target gas/vapor. If the target gas is present in an air sample drawn through the tube, a color change will occur in the reagent layer of the tube that depends on the contaminant's concentration. The sample is pulled via either a manual piston pump or a battery-operated motorized pump. There is a wide range of different tubes, specific to different compounds or groups of compounds, and having various effective concentration ranges. The chemistries relied upon to effect the color changes in the tubes are specific to the individual compounds and the reactive reagent.

For example, the Draeger tube for styrene is based on the reaction of styrene with formaldehyde in the presence of sulfuric acid to form a red-brown color stain in the tube.

A few of these devices rely on air contact with the tube through diffusion, and thus operate passively. Tubes used with battery-operated pump or those that sample the air through diffusion are used to determine time-weighted average concentrations of the workplace air contaminant of interest, while all the tubes used with a hand-operated vacuum pump are intended for measuring more or less instantaneous concentrations. The Safety Equipment Institute (USA) currently certifies chemical indicator tubes based on American National Standards Institute/International Safety Equipment Association standard 102 (1996).

## Quality Assurance Aspects of Workplace Air Analysis

Quality assurance is a set of operating principles that, if strictly followed during sample collection and analysis, will produce data of known and defensible quality. The reliability of analytical results depends on many factors such as the personnel performing the tests, environmental conditions, test methods, validation of test methods, equipment functioning, measurement traceability, sampling, and the storage and handling of samples. To minimize all the negative impacts of these factors, a properly validated, documented standard operating procedure must be used for all workplace air analysis. This standard operating procedure should include, but are not limited to, the following elements: acceptable sampling/

analysis devices and procedures, proper transportation and storage conditions, calibration requirements for both field and laboratory instrumentation, estimation of measurement uncertainties, and acceptable ranges for spike recovery efficiencies.

There are other routinely practiced procedures in terms of intralaboratory and interlaboratory quality control, such as the control chart, round-robin interlaboratory testing, and various proficiency tests offered by different agencies, such as the PATs (Proficiency Analytical Testing) by AIHA in the US and WASPs (Workplace Analysis Scheme for Proficiency) by the Health and Safety Laboratory in Great Britain. In normal circumstances, a combination of these quality control measures should be used in performing workplace air analysis.

## Definition and Classification of Alkaloids

An alkaloid has been defined by Pelletier as: “a cyclic organic compound containing nitrogen in a negative oxidation state which is of limited distribution among living organisms”.

Most alkaloids have basic properties connected with a heterocyclic tertiary nitrogen. Notable exceptions are colchicine, caffeine, and paclitaxel. Most alkaloids are biosynthetically derived from amino acids such as phenylalanine, tyrosine, tryptophan, ornithine, and lysine. Alkaloids represent a wide variety of chemical structures. About 20 000 alkaloids are known, most being isolated from plants. But alkaloids have also been found in microorganisms, marine organisms such as algae, dinoflagellates, and puffer fish, and terrestrial animals such as insects, salamanders, and toads.

Alkaloids are often classified according to their molecular skeleton, e.g., the two largest groups are the indole alkaloids and isoquinoline alkaloids (each more than 4000 compounds). Other important groups are tropane alkaloids (~300 compounds), steroidal alkaloids (~450 compounds), and pyridine and pyrrolizidine alkaloids (respectively, ~250 and 570 compounds).

Classification based on botanical origin of the alkaloids are also used, e.g., *Papaver* (opium) alkaloids, *Cinchona* alkaloids, *Rauvolfia* alkaloids, *Catharanthus* alkaloids, *Strychnos* alkaloids, Ergot alkaloids, cactus alkaloids, and *Solanum* alkaloids. The structures of some alkaloids are shown in **Figure 1**.

Many alkaloids have strong biological activities in man. In part this can be explained by structural relationship with important signal compounds (neurotransmitters) such as dopamine, acetylcholine, noradrenaline, and serotonin. The fact that alkaloids are water soluble under acidic conditions and lipid soluble under neutral and basic conditions give them unique properties for medicinal use, as they can be transported in the protonated form, and can pass membranes in the neutral form. In fact most synthetic medicines do contain one or more tertiary nitrogens.

A number of alkaloids have commercial interest as medicines or tools in pharmacological studies (see **Table 1**). Both pure compounds and plants (or extracts

**Figure 1** Structures of some different types of alkaloids.

**Table 1** Some alkaloids of pharmaceutical interest

Ajmalicine	Physostigmine
Ajmaline	Pilocarpine
Quinine	Veratrine
Quinidine	Solasodine
Strychnine	Harringtonine
Reserpine	Ephedrine
Rescinamine	Mescaline
Yohimbine	Aconitine
Vincamine	Nicotine
Vinblastine	Tetrodotoxin
Vincristine	Saxitoxin
9-Hydroxyellipticine	Sparteine
Camptothecin	Lobeline
Emetine	Muscarine
Atropine (1-hyoscyamine)	Serotonin
Scopolamine	Harmane
Cocaine	Psilocybine
Codeine	Caffeine
Morphine	Theophylline
Thebaine	Theobromine
Papaverine	Taxol
Narceine	Ergotamine
Narcotine	Ergonovine
Berberine	Ergosine
Sanguinarine	Ergocristine
Tubocurarine	Ergocryptine
Boldine	Ergocornine
Colchicine	Lysergic acid

thereof) containing alkaloids are used. Furthermore some alkaloids are widely found as drugs of abuse (e.g., mescaline, cocaine, psilocybin, psilocin, morphine, and its semisynthetic derivative heroin), as doping compounds (e.g., strychnine, ephedrine, caffeine), and as poisons (e.g., strychnine, pyrrolizidine alkaloids, coniine, nicotine, tetrodotoxin). Consequently, methods for the determination of alkaloids can be found in quite different contexts, mainly dependent on the matrices in which the alkaloids are found.

## Chemical Properties and Artifact Formation

Many alkaloids are difficult to crystallize as free base, but do crystallize as a salt. Most alkaloids have basic properties. The  $pK_a$  values vary from 6 to 12, with most alkaloids in the range of 7–9. In general the free base is soluble in organic solvents and not in water. Protonation of the amine function under acidic conditions usually results in a water-soluble compound. This characteristic is widely used in the selective isolation of alkaloids. Quaternary alkaloids are poorly soluble in organic solvents but are soluble in water at any pH.

Most alkaloids are colorless—only a few highly conjugated compounds are colored (e.g., berberine, sanguinarine, serpentine) or show strong fluorescence (e.g., quinine).

Alkaloids are often quite unstable, and N-oxidation in particular is quite common. Besides the effect of heat and light, their stability is influenced by solvents. Halogenated solvents are widely used in alkaloid research, and chloroform in particular is one of the most suitable because of its relatively strong proton donor character. However, these solvents are very reactive in terms of artifact formation. In chloroform (N-)oxidations occur easily. Furthermore peroxides in ethers may cause N-oxidations. With dichloromethane quaternary N-dichlorometho compounds may easily be formed. Similar compounds are formed with minor impurities present in chloroform. But also chloroform itself may react with an alkaloid to give artifacts. The decomposition product formed from chloroform by oxidation, phosgene, reacts with ethanol that is always present in this solvent. This product ethyl chloroformate reacts with tertiary nitrogens to yield ethylcarbamates. Alkaloids are in general more stable in toluene, ethyl acetate, and alcoholic solutions. In case of alkaloids containing a carbinolamine function, reactions with alcohols will occur (e.g., O-methyl pseudostrychnine is formed from pseudostrychnine with methanol). The 1–2% of ethanol in chloroform may also result in ethyl-derivatives. Ketones such as acetone and methyl ethyl ketone are well-known artifact formers, as

they can react both with carbinolamines and amines. Berberine for example may react with acetone. Ammonia and acetone may react during column chromatography on silica, yielding conjugates that give a Dragendorff-positive reaction. Ammonia may also react with aldehydes present in plant materials. Giving rise to artificial alkaloids, e.g., gentianine, which is formed from sweroside during extraction.

## Extraction

Alkaloids can be extracted under neutral or basic conditions (after basification of the plant material or biofluid to pH 7–9 with ammonia, sodium carbonate, or sodium hydrogencarbonate) as free base with organic solvents (e.g., dichloromethane, chloroform, ethers, ethyl acetate, alcohols). Some alkaloids can only be extracted at higher pH (>10) e.g., tryptamine. On the other hand alkaloids containing phenolic groups (e.g., morphine) are deprotonated at higher pH, and are thus not extracted by organic solvents under such conditions. Alkaloids can also be extracted in the protonated form (after acidification to pH 2–4 with dilute acids such as phosphoric acid, sulfuric acid, or citric acid) with water or alcohols (e.g., methanol). Also acetic acid and trifluoro acetic acid can be used for acidification. However, because of their lipophilic properties they will lead to ion-pair formation with the alkaloids, which in case of liquid–liquid extraction of the acidic aqueous extract with an organic solvent will pass into the organic phase (see below). A 0.1% trifluoroacetic acid solution in water as such is a very efficient solvent for alkaloid extraction from plant material which can directly be used for high-performance liquid chromatography (HPLC) analysis.

Further purification of alkaloids can be done by liquid–liquid extraction or liquid–solid extraction.

In liquid–liquid extraction the alkaloids are, after basification, extracted from an aqueous solution with an immiscible organic solvent (e.g., dichloromethane, diethyl ether, ethyl acetate, chloroform), or from an organic solvent with an aqueous acid. With the aid of ion-pairing agents (e.g., alkylsulfonic acids), alkaloids can be extracted from an acidic aqueous solution with organic solvents. It should be noted that common ions such as  $Cl^-$ ,  $Br^-$ ,  $I^-$ , acetate, and trifluoroacetate also result in the formation of ion-pairs which are readily soluble in organic solvents.

For liquid–solid extractions there are several possibilities. Reversed-phase materials such as chemically bonded  $C_8$  and  $C_{18}$  on silica are widely used. Also ion-exchange materials are used for the selective extraction of alkaloids.

For preparative purposes purifications based on precipitation of alkaloids are employed. A crude

extract of the alkaloids is made with aqueous acid. Subsequently the alkaloids are precipitated with reagents such as Mayer's reagent (1 mol l<sup>-1</sup> mercury(II) chloride in 5% aqueous potassium iodide) or Reinecke's salt (5% aqueous ammoniumtetrathio-cyanatodiammonochromate in 30% acetic acid) at pH 2, or picric acid (saturated aqueous solution) at pH 5–6. After collection by filtration or centrifugation, the precipitate is dissolved in an organic solvent (e.g., acetone–methanol–water, 6:2:1 (v/v/v)). The complexing substance is then removed by means of an anion exchanger. This method is particularly suited for the purification of quaternary alkaloids.

## Detection Reactions

Numerous reactions have been described for the detection of alkaloids in aqueous solutions. The most common are precipitation reactions such as Dragendorff's reagent (bismuth iodide), Mayer's reagent, picric acid, and Reinecke's salt (see above). All these reagents are more or less specific for protonated tertiary nitrogens (and quaternary nitrogens). Dragendorff's reagent is also used for the detection of alkaloids on thin-layer chromatography (TLC) plates. It may cause false-positive reactions with, for example, compounds containing conjugated carbonyl or lactone functions.

## Chromatographic Analysis

### Thin-Layer Chromatography

TLC is widely used in the analysis of alkaloid extracts. Particularly in the analysis of plant materials it offers the advantage of molecules with a broad range of polarities being separated in a single analysis. Also it does not require extensive sample cleanup of crude

extracts as in case of gas chromatography (GC) and HPLC. The most widely used stationary phase is silica. Alumina plates have been applied in the past, but are nowadays rarely employed. Reversed-phase materials such as chemically bonded C<sub>18</sub> on silica are also applied, but because of problems of tailing, the much cheaper silica plates are still widely employed.

In the case of strongly basic alkaloids, severe tailing may occur on silica gel plates because of the acidic properties of this adsorbent. Therefore, mobile phases containing bases like ammonia or diethylamine are widely used. Alternatively, TLC plates impregnated with basic solutions have been employed. For the detection of highly polar quaternary alkaloids and N-oxides, solvent systems consisting of methanol and aqueous salt solutions are useful. In Table 2 some widely used TLC systems are summarized.

Many methods have been reported for the detection of alkaloids on TLC plates. Besides quenching of ultraviolet (UV) radiation on fluorescent plates, general reagents for selectively detecting alkaloids are Dragendorff's reagent (orange-brown spots) and potassium iodoplatinate reagent (violet-purple spots) (Table 3). There is less risk of false-positive reactions with the latter (see above). Highly selective reagents have been reported for the various classes of alkaloids (see Table 4). These are based on different colorations under strongly oxidizing conditions.

### Gas Chromatography

Although alkaloids are nonvolatile, many alkaloid mixtures have been analyzed successfully by GC, especially capillary GC. Generally stationary phases with a low or sometimes intermediate polarity are used. Though hardly used anymore, for packed columns basic deactivation of the supporting material will improve peak shapes. For capillary columns

**Table 2** Some common for alkaloid analysis

<i>Solvent system (all with silica plates)</i>	<i>Commonly used ratios (v/v)</i>	<i>Polarity range<sup>a</sup></i>

 (B) 40% Potassium iodide in water.  
 (A) and (B) are mixed (5:2) and the spray reagent is prepared by mixing 50 ml of the stock solution with 100 g tartaric acid and 500 ml water.  
 Colors observed after spraying: orange–brown spots for alkaloids.

*Potassium iodoplatinate reagent*

The reagent prepared freshly by mixing 3 ml of 10% aq. hexachloroplatinic acid solution with 97 ml of water and 100 ml of 6% aqueous potassium iodide solution.

Colors observed after spraying: violet–purple spots for alkaloids.

**Table 4** Some selective color reactions for the detection of alkaloids on TLC plates

Treatment	Alkaloids detected
0.2 mol l <sup>-1</sup> iron(III) chloride in 35% perchloric acid: heat	Indole alkaloids, isoquinoline alkaloids
1% Cerium(IV) sulfate in 10% sulfuric acid	Indole alkaloids
1% p-dimethylaminobenzaldehyde in ethanol, followed by exposure to hydrochloric acid vapor	Ergot alkaloids
Sulfuric acid: heat	Various alkaloids

usually a length of 10–25 m is chosen. High temperatures for injection (200–300°C) and column (temperature gradients from 100°C to 250°C) are generally required. By using nitrogen specific detectors high selectivity can be obtained. The combination of GC with mass spectrometry (MS) has been fruitfully used for alkaloid analysis.

### Liquid Chromatography

For alkaloid analysis, liquid chromatography (LC) has developed into an important tool. Most separations are done on reversed-phase materials (C<sub>8</sub>-, C<sub>18</sub>-, and phenyl-bonded phases on silica), a major problem being extensive tailing arising from the interaction of the basic nitrogen and residual acidic silanol groups in the reversed-phase materials. Strong bases in particular show this problem. By adding long-chain alkylamines (e.g., hexylamine) in low concentrations (typically 1 mmol l<sup>-1</sup>) to the mobile phase, tailing can be reduced considerably. Also addition of amines like triethylamine or tetramethylammonium can be helpful in reducing tailing. Presently many special treated columns are available that show improved peak shapes for basic compounds. For these special treated columns selectivity and efficiency can vary considerably between brands,

**Table 5** General outlines of reversed-phase LC systems for the separation of alkaloids

Stationary phase	Mobile phase
C <sub>8</sub> -, C <sub>18</sub> - or phenyl-bonded phase with low percentage of free silanol groups.	<p><i>Ion-suppression mode</i>: methanol (acetonitrile)–water containing ~0.01–0.1 mol l<sup>-1</sup> phosphate buffer, ammonium carbonate or sodium acetate (pH 4–7).</p> <p><i>Ion-pair mode</i>: methanol (acetonitrile)–water containing ~0.005 mol l<sup>-1</sup> alkylsulfonate and 1% acid (e.g. acetic acid), pH 2–4.</p>

**Table 6** Mobile phases used for isocratic LC separation of alkaloids, with silica gel as the stationary phase

		Triethylamine												
		(~1% of the mobile phase)												

and plate numbers are usually lower than obtained for neutral test compounds on the same column. Less common is the use of polymeric-, ion-exchange, and aminopropyl-type columns.

Because of the equilibrium between free base and protonated alkaloid, the pH of the mobile phase has to be controlled. As silica-based stationary phases are unstable at higher pH (above 8), usually a pH between 2 and 4 is used. Both ion-suppression and ion-pairing modes are employed. Some general features of reversed-phase LC systems are given in **Table 5**. Isocratic separation using silica has been reported (**Table 6**), but despite the large selectivity offered, they are not commonly used anymore. The systems usually are similar to those applied in TLC.

For detection, UV absorption is most widely used. Some alkaloids can also be detected by means of their fluorescence. Some type of alkaloids have poor UV-absorptive properties, e.g., tropane alkaloids, pyrrolizidine alkaloids, and steroidal alkaloids, necessitating detection at a lower wavelength (200–220 nm). Electrochemical detection has been applied for alkaloids, enabling selective detection in the presence of interfering compounds.

MS coupled with LC is the most selective detection for alkaloids. As all-volatile eluents are needed for LC–MS, the acidic eluents often contain formic acid, acetic acid, or trifluoroacetic acid.

### Capillary Electrophoresis

Because of their ionic nature alkaloids can be analyzed by capillary zone electrophoresis. Low

pH-buffers can be used for the analysis of alkaloids (e.g., a pH 2.5 phosphate buffer). For closely related compounds capillary electrophoresis (CE) selectivity might be a problem as the charge-to-mass ratios are very similar. Capillary electrochromatography can also be used, but residual silanol groups in the stationary phase may cause tailing, similarly as in HPLC.

### Countercurrent Chromatography

The preparative isolation of alkaloids can be done with modern countercurrent chromatography. Because of the ionic nature of alkaloids, ion-pair gradients can be used to improve separation. Possible two-phase solvent systems are chloroform-methanol-aqueous phosphate or citrate buffer, pH ~4, containing perchlorate, acetate, or chloride as ion-pairing agent. Also pH-zone refining is a powerful tool for the large-scale separation of alkaloids.

## Spectrometric Techniques

### Nuclear Magnetic Resonance Spectrometry

For identification and structure elucidation,  $^1\text{H}$  nuclear magnetic resonance (NMR) spectrometry is a very useful tool in alkaloid research. With modern NMR high-field NMR spectrometers (300–800 MHz)  $^1\text{H}$  NMR-spectra can be obtained from 0.01 to 1 mg quantities of alkaloid. For identification such spectra are usually conclusive in most cases. For more complex two-dimensional spectra, e.g., in the case of complete assignment of the spectra of new compounds, larger amounts of sample are necessary. The usual solvent is deuterated chloroform. Small amounts of acid (e.g., as impurity caused by decomposition of chloroform) cause large shifts (up to 1–2 ppm) for protons close to the nitrogen. The shift is dependent on the degree of protonation of the nitrogen. This phenomenon can be used to improve spectral resolution and to identify signals close to the protonated nitrogen, i.e., not only adjacent protons are affected, but also those which are spatially close. Trifluoroacetic acid can thus be used as shift reagent in the analysis of  $^1\text{H}$  NMR-spectra of alkaloids.  $^1\text{H}$  NMR can also be used for the quantitation of alkaloids in crude extracts (e.g., caffeine, ephedrine, and pyrrolizidine alkaloids) or pharmaceutical formulations.

$^{13}\text{C}$  NMR spectrometry is likewise a major tool in structure elucidation of alkaloids. However, larger amounts of material are needed (1–10 mg). Shifts caused by acidic impurities may also occur, but are relatively less dramatic than in  $^1\text{H}$  NMR spectrometry.  $^{15}\text{N}$  NMR spectrometry has been applied to

alkaloids, but due to problems of sensitivity, its application is limited.

### Mass Spectrometry

The fragmentation of alkaloids has been studied extensively. MS is therefore a major tool in the identification and structure elucidation of alkaloids. In combination with GC and LC it is very useful in the quantitative analysis in complex mixtures of alkaloids, e.g., in plant or other biological materials. Solvent systems suited for LC-MS should only contain volatile compounds, i.e., the salts used in reversed-phase eluents should also be volatile (e.g., ammonium acetate, ammonium carbonate, ammonium formate, trifluoroacetic acid).

### Introduction

Amino acid analysis is one of the most widely employed analytical procedures. It is utilized in the elucidation of the structure of proteins, the diagnosis of disease states, and the determination of the nutritional value of foods, to name just a few examples. Sample types can be divided into two broad categories, protein hydrolysates and biological samples.

For the determination of the amino acid composition of a protein, a highly purified sample is hydrolyzed under acidic conditions to its constituent amino acids. The amino acid composition of the protein is determined from the concentrations of the individual amino acids and from the molecular weight of the protein. Because the protein sample is normally very pure, the composition of the hydrolysate is limited to amino acids commonly found in proteins. One does not have to be concerned about other endogenous amines that may interfere with the analysis. Most commercial amino acid analyzers quantify only the 20 amino acids commonly found in proteins. Therefore, the biggest challenge for this application is to produce a method with adequate sensitivity to accurately determine the amino acid composition of very small amounts ( $<1\text{ }\mu\text{g}$ ) of protein isolated from gels or nitrocellulose membranes.

The determination of amino acids in physiological samples presents a different set of challenges. Blood, urine, cerebrospinal fluid, and tissue samples are the most common types in this category. In these cases the amino acid composition of the mixture is usually not well defined. The total number of amino acids to

be determined may be smaller or larger than for protein hydrolysates, depending on the sample type and the goals of the analysis. Many nonprotein amino acids, such as taurine and  $\gamma$ -aminobutyrate (GABA), are included in the assay of physiological amino acids. In contrast to protein hydrolysates, which are fairly 'clean' samples, most biological fluids and tissues contain endogenous amines that may interfere with the determination of the amino acids.

### Qualitative Spot Tests

Amino acids lack a distinguishing chromophore; therefore, detection is almost always based on the reaction of the amine with a derivatizing reagent. For a simple spot test, it is necessary to choose a reagent that reacts quickly to give a product possessing different spectroscopic properties from the parent reagent. Examples of this type of reagent include ninhydrin, 1-fluoro-2,4-dinitrobenzene, fluorescamine, and *o*-phthalaldehyde (OPA). The resulting absorbance or fluorescence reading will provide an indication of the total amount of amino acid present in the sample.

### Colorimetry

The simplest method for the determination of amino acids is reaction with ninhydrin. Ninhydrin reacts with both primary and secondary amino acids to produce Ruhemann's purple, which can be detected by ultraviolet (UV)–visible spectroscopy. The reaction requires heat, and a reducing agent is generally added to stabilize the color formation. Primary amines are detected with the greatest sensitivity at 570 nm, while the absorption maximum for secondary amines is 440 nm. If both primary and secondary amines are to be determined, a common absorption wavelength of 500 nm is employed; however, this leads to decreased sensitivity. Under optimal

conditions, a minimum of 5–10 nmol of material is required for detection.

Sanger's reagent, 2,4-dinitrofluorobenzene, can also be employed for the colormetric detection of amino acids. The reagent reacts with both primary and secondary amines and derivatives are detected at 420 nm. The molar absorptivity of the reagent is  $10^4$ , allowing quantification of amino acids at the micromolar level. The reagent also reacts with thiols and alcohols, but these products are relatively unstable.

### Fluorimetry

Fluorescamine is employed for more sensitive determination of amino acids by fluorescence spectroscopy. Since it undergoes rapid hydrolysis under aqueous conditions, the reagent is normally dissolved in acetone. It is commonly employed for the detection of amino acids on surfaces, such as thin-layer chromatography (TLC) plates. Amino acids are detected based on emission of light at 470 nm following excitation at 390 nm. Detection limits for amino acids are in the low picomole range.

OPA can also be employed for the detection of mixtures of amino acids. It reacts with primary amines in the presence of mercaptoethanol or other thiols to produce highly fluorescent isoindole derivatives (excitation wavelength 340 nm, emission 455 nm). In contrast to that with ninhydrin, this

reaction proceeds rapidly at room temperature and is complete in less than 1 min. The OPA and the thiol can be added to a basic solution of amino acids to provide a measurement of the total amino acid content based on a fluorescence measurement.

## Chromatographic Methods

### Ion-Exchange Chromatography

The determination of concentrations of individual amino acids in mixtures demands a separation step. The classical method employs cation-exchange chromatography using a strongly acidic sulfonated polystyrene/divinylbenzene copolymer as a support. These columns are very rugged and can withstand concentrated acids, bases, and large amounts of organic solvents. Amino acids are normally eluted with an acidic mobile phase. A typical chromatogram using cation-exchange chromatography is illustrated in **Figure 1**.

### Direct detection

*UV spectroscopy* Amino acids can be detected directly in chromatographic eluents by absorbance spectroscopy at 200 nm with detection limits between 1 and 10 pmol. However, there are several drawbacks to this method of detection for liquid chromatography (LC). The first is a lack of selectivity

**Figure 1** Separation of amino acids by cation-exchange chromatography and postcolumn reaction with ninhydrin. (Courtesy of Biochemical Research Service Laboratory, University of Kansas; used by permission.)

in biological samples, since there are many other endogenous compounds that absorb at this wavelength. Second, many of the solvents employed in LC also absorb at 200 nm, leading to a high background signal if they are present in the mobile phase.

**Pulsed amperometric detection (PAD)** Amino acids are not generally considered to be electrochemically active because products of the oxidation accumulate on the electrode surface and prevent it from participating in any further electrochemical processes. This problem can be overcome if PAD is employed. Amino acids are generally detected using a platinum electrode under alkaline conditions ( $0.25 \text{ mol l}^{-1}$  NaOH) using a triple-pulse waveform with  $E_1$ ,  $E_2$ , and  $E_3$  at 0.50,  $-0.89$ , and  $0.70 \text{ V}$ , respectively. Due to the basic conditions required for the detection of amino acids, a base-stable anion-exchange column must be employed. Detection limits of  $50 \text{ pmol}$  have been obtained for phenylalanine and methionine using this technique.

**Direct amperometry** Direct detection of amino acids can be accomplished with nickel and copper electrodes. The oxidation occurs under only neutral or basic conditions; therefore, the separation is limited to silica- or polymer-based columns. Cation-exchange chromatography, which requires acidic conditions, cannot be used unless base is added postcolumn.

In the case of the nickel electrode, detection is performed at  $+0.49 \text{ V}$  versus the standard calomel electrode. At this potential,  $\text{Ni}^{3+}$  is present on the electrode surface. The  $\text{Ni}^{3+}$  is reduced in the presence of the amino acids to  $\text{Ni}^{2+}$ . The current produced is proportional to the concentration of the amino acid. Detection limits for glycine have been reported to be in the low nanogram range.

Amino acids can also be determined by amperometric detection with a copper electrode under neutral or alkaline conditions. This method is very selective, with the working electrode potential set at only  $+0.10 \text{ mV}$  versus  $\text{Ag}/\text{AgCl}$ . In this detection method, amino acids complex with  $\text{Cu}^{2+}$  ions present on the electrode surface, producing a response that is proportional to the concentration of the amino acid. Detection limits are between  $10$  and  $100 \text{ pmol}$  and can be improved if microbore chromatography is employed. The slower flow rates utilized with microbore chromatography columns allow more time for complexation to take place, thus improving the detection limits.

**Postcolumn derivatization** Although amino acids can be determined directly following cation-exchange

chromatography using the detection methods discussed above, the most prevalent technique for increasing the sensitivity is postcolumn addition of a derivatizing reagent. The resulting derivatives can then be detected by UV or fluorescence detection. Several of the reagents employed for postcolumn derivatization such as ninhydrin, fluorescamine, and OPA are also used to determine total amino acids.

Ninhydrin was the first reagent utilized for the detection of amino acids following cation-exchange chromatography, and it is still very popular today. For liquid chromatographic determinations, dual wavelength and diode array absorbance detectors are often used to detect both primary and secondary amino acids with good sensitivity. However, if sensitivity is not important, both species can be determined at a wavelength of  $500 \text{ nm}$ . Detection limits using the optimum wavelengths are  $\sim 50 \text{ pmol}$ .

Because it is based on UV absorption, the use of ninhydrin is the least sensitive method for the determination of amino acids. It also has the disadvantage that the reaction coil must be heated to  $130^\circ\text{C}$  in order for the postcolumn chemistry to occur in the minimum amount of time. In addition, the reagent reacts with ammonia, which leads to baseline instability if buffers containing trace ammonia are employed to make up the mobile phase.

For increased sensitivity, reagents that yield fluorescent products are employed. These include OPA, fluorescamine, and 4-fluoro-7-nitro-benzo-2-oxa-1,3-diazole (NBD-F). Derivatization with OPA provides the best limits of detection for most amino acids. Although the products of OPA derivatization are unstable and decompose fairly rapidly to produce nonfluorescent 2,3-dihydro-1H-isoindol-1-ones, this is not a problem with postcolumn derivatization since the products are detected almost instantaneously.

One of the drawbacks of OPA is that it reacts only with primary amines. Proline can be determined if sodium hypochlorite or chloramine T is added to the postcolumn reagent. Under these conditions, proline is converted to aminobutyraldehyde, which reacts with OPA. The addition of hypochlorite can be accomplished in two ways. It can be pulsed in at the time of elution of proline. This provides the highest sensitivity for the primary amino acids, but causes a baseline disturbance around the elution time of proline. It also requires computerized equipment for precise control of the timing of the pulse. The second possibility is to add hypochlorite to the mobile phase, but this causes a decrease in response for the primary amino acids due to their conversion to chloramines. Another problem that occurs with OPA is that the derivatives of lysine and cysteine exhibit fluorescence

quenching. However, the fluorescence response can be revived by addition of Brij 35 to the mobile phase. Despite these drawbacks, the sensitivity of this method is better than those of the competing postcolumn methods, with detection limits for amino acids in the 1–2 pmol range.

Fluorescamine has also been employed for postcolumn derivatization with fluorescence detection. As discussed previously, a fluorescent product is generated in the presence of primary amines within a few seconds. Fluorescamine undergoes hydrolysis, but the hydrolysis reaction is much slower than the reaction with primary amines and the product of that reaction does not fluoresce. For postcolumn addition, the reagent is added as a solution in acetone, acetonitrile, or methanol. As with OPA, proline can be detected through conversion to aminobutyraldehyde by oxidation with *N*-chlorosuccinimide. Unlike OPA, fluorescamine reacts poorly with ammonia. Therefore, problems with baseline drift are not as prominent. Since the reaction of fluorescamine with primary amines produces an equilibrated mixture of two products, it is used most frequently as a postcolumn reagent.

4-Chloro-7-nitrobenzo-2-oxa-1,3-diazole (NBD-Cl) and 4-fluoro-7-nitrobenzo-2-oxa-1,3-diazole (NBD-F) can also be employed for postcolumn detection of amino acids. The reagents also react with alcohols and thiols, but are most reactive toward amines. NBD-F is 50–100 times more reactive than NBD-Cl and is therefore the preferred form for postcolumn derivatization. Unlike OPA and fluorescamine, NBD-F can be used for the determination of both primary and secondary amines. The excitation and emission wavelengths for the NBD-amino acids are 470 and 530 nm, respectively. The longer emission wavelength characteristic of this reagent makes it more selective for the analysis of biological materials. The fluorescence is pH dependent and is highest at low pH. Therefore, to obtain the best sensitivity, HCl must also be added postcolumn to enhance fluorescence quantum yield.

Although there is an increasing trend toward precolumn derivatization methods, there are several advantages to an ion-exchange separation with postcolumn derivatization. The first is that there is little sample preparation; protein hydrolysates can be injected directly into the column for analysis by LC. Unlike precolumn methods, it is not necessary to separate reaction side-products from the reaction mixture; instead, they become a source of background. With postcolumn methods there is more sample-to-sample consistency because of the robustness of the ion-exchange separation and the fact that the reaction time is determined by the column size.

When using postcolumn derivatization, the reaction does not have to go to completion and can produce multiple products. These do not affect the precision of the method as long as the mixing time and product ratio are reproducible. Finally, the derivatives do not have to be stable; they can start to degrade immediately after detection.

Two of the problems inherent in postcolumn derivatization are difficulties with baseline stability due to impurities in the mobile phase and late-eluting peaks. Ammonia, in particular, can interfere with the detection of the basic amino acids. Also with postcolumn derivatization, the reaction conditions are restricted by the mobile phase used for the separation. Frequently, the column effluent must be adjusted to achieve optimal reaction conditions, including pH. Loss of resolution due to band broadening produced by the reaction coil employed for mixing the reagent with the column effluent can also be a problem. However, 'knitted coils' are now available that produce very little or no band broadening. Finally, equipment and reagent costs are much higher than with precolumn derivatization.

### Reversed-Phase Liquid Chromatography

Reversed-phase LC is becoming increasingly popular for the separation of amino acids. Reversed-phase columns are readily available commercially and exhibit higher efficiencies than most commercially available ion-exchange columns. They are also compatible with aqueous samples, since water is generally a major component of the mobile phase. Therefore, it is not necessary to employ additional sample preparation steps in order to produce a sample in a nonaqueous environment.

**Precolumn derivatization** For separation by reversed-phase chromatography, precolumn derivatization is a necessity. The derivatization step increases not only detectability of the analyte but also its hydrophobicity, which makes the separation of the amino acids by reversed-phase chromatography possible. Several precolumn derivatization reagents are available. These include OPA, naphthalenedialdehyde (NDA), dimethylaminonaphthalene sulphonyl chloride (DANSYL), phenyl isothiocyanate (PITC), and *N*-(9-fluorenyl)methoxycarbonate (Fmoc).

Reagents based on dialdehyde chemistry have been shown to be highly sensitive for fluorescence and/or electrochemical detection of amino acids. They are both fluorogenic and electrogenic; that is, the compounds themselves are not fluorescent or electroactive but produce derivatives that exhibit both properties. The overall reaction scheme for these

**Figure 2** Reaction of aromatic dialdehydes with primary amines to form isoindole derivatives. Nu, nucleophile.

types of compounds is shown in **Figure 2**. OPA reacts very quickly with primary amines, but the derivatives produced are not very stable. Therefore, almost all precolumn derivatization employing OPA is done with an automated sample preparation system that can add reagents to the sample and precisely monitor the reaction time. More stable derivatives can be produced if either *t*-butyl thiol or thiosulfate is employed as the nucleophile. However, these derivatives are not fluorogenic and thus can only be assayed by electrochemical detection. Detection limits for OPA derivatives of amino acids are frequently reported to be less than 1 pmol.

Recently, an analog of OPA, NDA, which yields more stable derivatives, was introduced. NDA reacts with primary amines in the presence of cyanide to produce highly fluorescent cyanobenz-[f]isoindole (CBI) derivatives. The reaction time is ~20 min, as opposed to 2 min with OPA. However, the resulting CBI derivatives are considerably more stable than their OPA/mercaptoethanol counterparts; most derivatives exhibit little or no degradation after 16 h in the dark. Detection limits as low as 100 fmol have been reported.

Because both of these reagents exhibit fluorescence quenching, problems arise in the determination of lysine and cysteine. Since they also react only with primary amines, special steps must be undertaken to detect proline.

The DANSYL reagent reacts with both primary and secondary amines to produce fluorescent derivatives. These derivatives are very stable when stored in the dark and authentic standards are commercially available. One of the problems with this derivatization chemistry is hydrolysis of the reagent and the formation of multiple derivatives for several of the amino acids. In addition, there is fluorescence quenching in polar solvents, so detection limits using reversed-phase chromatography with UV detection are often comparable to that obtained by fluorescence. The limit of detection using UV detection is ~100 pmol.

PITC chemistry is becoming increasingly popular for the analysis of amino acids. This is extracted from the Edman degradation chemistry. The reaction scheme is illustrated in **Figure 3**. The most popular

**Figure 3** Reaction of primary and secondary amines with PITC. Formation of PTC and PTH amino acids.

way to detect amino acids using this chemistry is to perform only the first step of the Edman degradation reaction. The reaction conditions consist of derivatization of the amino acids for 5 min in a mixture of acetonitrile, pyridine, triethylamine, and water in the ratio 10:5:3:2 (v/v/v/v). Excess reagent is removed by vacuum and the sample is dissolved in mobile phase prior to injection. The phenylthiocarbamyl (PTC) derivatives that are produced can be determined by UV detection. Detection limits using this method have been reported to be as low as 1 pmol. PTC derivatives can be converted into phenylthiohydantoin (PTH) derivatives. However, this procedure adds a considerable amount of time to the assay procedure.

FMOC is a reagent that reacts quickly with both primary and secondary amino acids. Excess reagent must be removed rapidly because it undergoes hydrolysis. The excitation and emission wavelengths are 270 and 315 nm, respectively. An increasingly popular method for amino acid analysis is to measure the primary amino acids with OPA and the secondary amino acids with FMOC. Samples are derivatized first with OPA and then with FMOC. Primary amines are detected using the fluorescence properties of OPA while the secondary amines are detected using those of FMOC.

The advantages of precolumn over postcolumn derivatization include the ability to optimize reaction conditions without concern for their compatibility with the chromatographic conditions. Reaction time, pH, solvent, and reagent concentration can all be optimized to obtain the maximum yield of product.

Side-products (which create baseline noise in post-column methods) can be eliminated via a cleanup step or separated chromatographically from the peaks of interest.

Precolumn derivatization methods are not free from disadvantages. One is that side-products from the reaction can sometimes be difficult to separate from the peaks of interest. Also with precolumn derivatization, as its name implies, each sample must be derivatized prior to injection. This can add to the total analysis time. However, instrumentation is now available to derivatize several samples simultaneously in a closed system, which not only solves the sample preparation time problem but also results in highly reproducible chemistry. Since the reaction may not go to 100%, an internal standard is frequently necessary. Finally, the addition of a similar 'tag' to all the amino acids may make them more difficult to separate. Table 1 summarizes the properties of several pre- and postcolumn derivatizing reagents employed for amino acid analysis.

**Microbore and open-tubular chromatography** In order to increase the sensitivity of LC for the analysis of amino acids, the techniques of microbore and open-tubular chromatography are becoming increasingly important. These techniques provide greater mass sensitivity because there is less dilution of the sample as it moves down the chromatographic column. Separations in which capillaries of 100  $\mu\text{m}$  or less ID were used provided the capability of analyzing very small samples, including single cells. Figure 4 shows the determination of several NDA-derivatized amino acids in a single neuron by open-tubular LC.

### Capillary Electrophoresis

Capillary electrophoresis (CE) was first introduced in 1983. Since that time there have been numerous reports of the determination of amino acids by CE. The simplest system consists of a high-voltage power supply, two buffer reservoirs, a transparent plastic safety box, two platinum wires, a detector, and a fused silica capillary. The capillaries employed have very small diameters, generally between 5 and 100  $\mu\text{m}$ . In general, the same types of detectors are used as for liquid

**Figure 4** Chromatogram of NDA-tagged amino acids from a single E4 neuron from *Helix aspersa*. B1 and B2 are peaks present in blank runs. Trp is obscured by B2 and Ile, Phe, and Leu are the three peaks immediately following B2. IS1 and IS2 are internal standards norleucine and normetanephrine, respectively. All unlabeled peaks are unknown. (Reproduced with permission from Oates and Jorgensen (1990) *Analytical Chemistry* 62: 1575.)

chromatographic separations with some modifications. UV detectors are modified versions of commercially available instruments. Fluorescence detectors usually rely on a laser as the excitation source because it is easy to focus on the capillary wall. Electrochemical detectors employ carbon fibers rather than the conventional glassy carbon disk electrodes.

In CE, the primary separation mechanism is based on charge. The different amino acids exhibit different electrophoretic mobilities, when a potential is applied across the capillary. However, due to the presence of ionized silanol groups on the fused silica surface, an electroosmotic flow is set up, which is greater than the electrophoretic mobility of the analytes. Therefore, all analytes, regardless of charge, migrate toward the cathode. Many of the amino acids are separated by CE using a fused-silica capillary and a simple alkaline buffer such as borate. However, in order to resolve the neutral amino acids completely, micellar CE is frequently employed. In this case, sodium octyl sulfate or another surfactant is added to the mobile phase. Derivatized amino acids partition in and out of the micelle, yielding a separation that is based both on sample hydrophobicity and charge.

One of the advantages of CE is that it can be employed for the analysis of very small samples. Generally, only a few nanoliters of sample are required for analysis. Hence, CE has been employed for the analysis of amino acids in single cells, small tissue extracts, and microdialysis samples. **Figure 5** shows a separation of NDA amino acids from a rat brain dialysate using CE with electrochemical detection.

### Thin-Layer Chromatography

If qualitative information is desired, TLC can be employed for amino acid analysis. Paper, silica gel,

and cellulose have all been employed for the separation of amino acids. Spots are normally detected by spraying the plate with a 0.1% solution of ninhydrin dissolved in acetone. The plate is heated for 10 min at 105°C. An alternative method of development is the use of ninhydrin containing cadmium acetate. This plate can be developed by soaking overnight in sulfuric acid. Quantification by scanning densitometry is also possible.

Combined TLC electrophoresis enhances the separation of amino acids. Amino acids are separated in one dimension on the TLC plate and then a voltage is applied across the other direction.

### Gas Chromatography

Gas chromatography (GC) has also been employed for the analysis of amino acids. The primary advantage of GC is that it can be combined with mass spectrometry (MS) for the identification of rare or unusual amino acids in biological samples.

**Derivatization** Most amino acids are nonvolatile and must be derivatized prior to separation by GC. Amino acids are both esterified and acylated to produce *N*(*O,S*)-acylamino acid esters, with the most common being *N*(*O,S*)-trifluoroacetyl-*n*-butylesters. Other alcohols of low relative molecular mass have also been employed for the esterification including methanol, propanol, isopropyl alcohol, butanol, or isobutyl alcohol. Several different acylating reagents have been explored as well, including acetic anhydride, trifluoroacetic anhydride, pentafluoropropion anhydride, or heptafluorobutyric anhydride.

To guarantee quantitative yields of ester derivatives, the amino acid extract must be free of water. Following derivatization, the reaction solvent is evaporated under nitrogen at low temperature to ensure that there is no loss of volatile esters. The amino acids are then acylated. Reaction conditions vary from 2 h at room temperature to 10 min at 150°C. Prior to injection, the solution is evaporated to dryness and reconstituted in a solvent compatible with GC. Arginine can cause problems in GC analysis due to its low volatility.

**Detection** Femtomole detection limits can be achieved using electron capture detection (ECD). Nitrogen-phosphorus and flame ionization detectors have also been employed. However, the primary advantage of GC is its compatibility with MS. Using a mass-selective detector, amino acids can be determined at the low femtomole level. **Figure 6** shows the

separation of amino acids as their *N*-TFA *n*-butyl esters present in a soy bean meal hydrolysate by GC-ECD.

### Mass Spectrometry

There are some cases in which MS has been employed for the determination of amino acids without a separation step. Amino acid samples derivatized with Sanger's reagent can be 'separated' based

**Figure 6** GLC analysis of soy bean meal hydrolysate. Experimental conditions: 25 mg of soy bean meal hydrolyzed for 22 h at 110°C; cleaned by cation exchange; approximately 18 µg total amino acid injected. (Reprinted with permission from Zumwalt RW, Kuo KCT, and Gehrke CW (eds.) (1987) *Amino Acid Analysis by Gas Chromatography*, vol. 1, p. 38. Boca Raton, FL: CRC Press; © CRC Press, Boca Raton, Florida.)

on mass using negative chemical ionization MS. **Figure 7** shows an example of a plasma sample derivatized by this reagent and analyzed by MS. Despite this illustration, MS is rarely used for the determination of mixtures of amino acids without being coupled to a separation step. Generally, *N*-perfluoroacetylaminobutyl esters are determined by GC-MS. Due to the high molecular weights of the *N*(*O,S*)-acylalkyl esters, chemical ionization (CI) is the preferred method of ionization. In CI, a reaction gas such as methane is introduced into the mass spectrometer producing  $\text{CH}_5$  and  $\text{C}_2\text{H}_5^+$  ions. These ions then react with the *N*(*O,S*)-acyl esters to produce an  $M+1$  ion through the addition of a proton. Methane is frequently employed as the carrier gas for GC experiments that employ MS as a detector.

In GC-MS, compounds can be analyzed in one of two ways. If compound identification is the object of the assay the detector is run in the scanning mode and a mass spectrum of the compound is obtained as the compound elutes from the gas chromatograph. Alternatively, selective ion monitoring (SIM) can be employed for increased sensitivity. In this case, only compounds containing a characteristic ion in their mass are detected. Using SIM, detection limits are 2–3 orders of magnitude lower than those with scanning detection (frequently as low as 0.1 pg for negative ion CI detection of an electronegative group).

Liquid chromatography-mass spectrometry (LC-MS) is also becoming an increasingly popular analytical tool. Derivatives employed for LC analysis with UV or fluorescence detection have also been studied by LC-MS. It is particularly useful for the identification of rare amino acids and verification of peak purity.

**Figure 7** Detection of amino acids in plasma as their dinitrophenyl amino acid methyl esters by negative ion chemical ionization mass spectrometry. (Reproduced with permission from the Ph.D. Dissertation of Todd Williams, University of Maine, December 1987; Figure 11, p. 99.)

## Special Problems

One of the biggest problems in trace amino acid analysis is contamination of the sample by environmental amino acids. A fingerprint placed on the side of glassware can consist of up to 10 pmol of several amino acids. When performing amino acid analysis of proteins, special care must be taken to avoid contamination of the sample. Glassware should be cleaned thoroughly and frequently pyrolyzed to assure no amino acid contamination. Gloves should be worn when preparing solutions and performing the derivatization. One should be certain to use high-purity reagents and chemicals.

For the detection of amino acids in biological samples, a protein precipitation step is generally necessary. For ion-exchange-based separations, sulfosalicylic acid is the most popular reagent. Because precolumn derivatization is almost always employed for reversed-phase systems, methanol (which does not affect the pH) is usually utilized as the precipitation reagent. For GC studies, picric acid is generally used. Once the protein has been removed, samples can be injected directly into a cation-exchange column or derivatized for reversed-phase LC and GC analysis. Further purification prior to injection is often accomplished using an ion-exchange cartridge.

In the case of amino acid analysis, the quantification of cysteine can be difficult because it is oxidized to cystine during acid hydrolysis. To circumvent this problem, cysteine can be oxidized to cysteic acid with performic acid prior to analysis. Alternatively, cysteine can be converted to the pyridyl ethyl derivative and subsequently detected by postcolumn reaction with ninhydrin. Still another method involves the production of carboxymethyl cysteine following alkylation with iodoacetic acid. All of these cysteine derivatives can be separated by either reversed-phase precolumn or ion-exchange postcolumn methods.

Overall, the analysis of amino acids at trace levels continues to be a challenging problem. Reversed-phase LC methods based on derivatization of the amino acids are still not as robust as classical ion-exchange methods, although they are frequently

more sensitive. The presence of contaminating amino acids in buffers and glassware continues to be a source of frustration for the analyst interested in quantifying amino acids at the subpicomole level. Further development of automated equipment for amino acid analysis should eliminate or greatly reduce contact with human skin and, thus, many of these contaminants.

## Introduction

Amperometry is an electroanalytical technique that involves the application of a constant reducing or oxidizing potential to an indicator (working) electrode and the subsequent measurement of the resulting steady-state current. Thus, the term ‘amperometry’ is derived from the current measurement unit, ‘ampere,’ and the measurement device, ‘meter,’ used in this method. Usually, the magnitude of the measured current is dependent on the concentration of the reduced or oxidized substance, and hence this method can be used for various analytical applications.

This method offers the ability to distinguish selectively between a number of electroactive species in solutions by judicious selection of the applied potential and/or choice of electrode material. In cases where a nonspecific potential is applied, the resulting current may be contributed by several electroactive species. The careful choice of the composition of the supporting electrolyte may also be useful in improving the selectivity of amperometric methods. In cases where oxygen interferes, its removal by purging the solution with an inert gas such as nitrogen or argon may be necessary.

Various analytical methods now employ amperometric measurements as part of their procedures. In particular, amperometric titrations have been widely used for the analysis of various substances in samples ranging from water to radioactive materials. Also, amperometric sensors, such as the dissolved oxygen probe and various amperometric biosensors, are widely used for clinical, environmental, and industrial monitoring. Furthermore, amperometric detectors have gained considerable use since the 1970s in high-performance liquid chromatographic determination of various substances and in flow injection analysis.

## Principles

The electrochemical oxidation or reduction of an electroactive species on a suitable electrode material by the application of the desired potential results in

either a steady-state anodic or cathodic current. (It is important to note that the current measured in such a system is distinctly different from the current usually measured in the so-called ‘galvanic cell’, which does not require the application of a potential.) According to the Cottrell equation, the resulting current can be related to the concentration of the electroactive species as follows:

$$I = \frac{nFAD^{1/2}C_b}{\pi t} \quad [1]$$

where  $I$  is the diffusion current ( $\mu\text{A}$ ),  $t$  is the electrolysis time (s),  $n$  is the number of electrons involved in the electrode reaction,  $F$  is the Faraday constant ( $96\,487\text{ C equiv}^{-1}$ ),  $A$  is the electrode area ( $\text{m}^2$ ),  $D$  is the diffusion coefficient of the electroactive species ( $\text{m}^2\text{s}^{-1}$ ), and  $C_b$  is the bulk concentration of the electroactive species ( $\text{mmol l}^{-1}$ ). The magnitude of the resulting current will thus be directly proportional to the concentration of the reduced or oxidized substance. This technique therefore provides a simple and reliable method for the quantification of various substances based on the relationship between the measured current and concentration of the analyte.

Owing to the time dependence of the resulting anodic or cathodic current, the reliable analytical utilization of amperometry requires measurement at a fixed time interval. However, the variable nature of the resulting anodic and cathodic currents can be useful in elucidating the electrochemical process(es) on various electrode surfaces. This has indeed led to the development of a variant of this technique, known as ‘chronoamperometry’, which involves the application of the desired anodic or cathodic potential and the subsequent measurement of the resulting current versus time. The main requirements in chronoamperometry are that:

1. The transport of the reactants and products to or from the electrode surface must be governed by diffusion without stirring of the solution.
2. The electrode surface must remain constant and must not be involved in the electrode process during the measurement.

The application of the desired potential to the electrode in amperometry results in a decrease in the concentration of the electroactive species on the electrode surface to zero due to the anodic or cathodic reaction(s) taking place at the vicinity of the electrode. In general, the rate of current change will vary

depending on the geometry of the chosen electrode and the diffusion properties of the substance. With a flat type of electrode, where linear diffusion is assumed, the rate of current change can also be expressed by the Cottrell equation as

$$\Delta I = \frac{nFAD^{1/2}C_b}{(\pi t)^{1/2}} \quad [2]$$

According to this equation, the current decreases toward zero with an increase in the electrolysis time and, hence, indicates that the concentration of the electroactive substance in the vicinity of the electrode decreases progressively with time. In situations where nonlinear diffusion of the electroactive substance to the electrode surface (i.e., spherical diffusion) is involved, the relationship between the rate of current change and other parameters are more complex.

The concept of chronoamperometry has been further extended to develop a more advanced variant known as 'double-potential-step chronoamperometry.' This mode of amperometry is of considerable interest in electrochemical research, and in pulsed amperometric detection in chromatography and flow injection analysis. In double-potential-step chronoamperometry, the applied potential is changed twice during the measurement, first by applying a potential to induce oxidation or reduction at the electrode surface, as in the normal amperometric mode. The potential is then changed again, after a short electrolysis time, to either the initial value or a new value. The second potential step is often chosen to enable the product of the initial electrode process to be converted back to either its original form or to another product. **Figure 1** shows how the choice of the second potential ( $E_2$ ) is successfully used to influence the sensitivity of a pulsed amperometric polypyrrole-based biosensor for urea. Evidently, improved sensitivity can be obtained for pulsed amperometric detection of urea with the biosensor by careful selection of the second applied potential.

The various modes in which amperometry can be employed have resulted in its extensive utilization in analytical chemistry – in amperometric titration, amperometric sensing, and amperometric detection in flowing systems. The various applications of amperometry are discussed below.

## Amperometric Titrations

### Basic Theory

The most important feature in amperometry is the linear relationship between the diffusion current and the concentration of the electroactive species (this also applies to other electroanalytical techniques

**Figure 1** Influence of the applied second potential on the pulsed amperometric detection of urea with a polypyrrole – urase biosensor.  $E_1$  was set  $-70$  mV, while  $E_2$  was varied. Pulse width was 120 ms.

such as polarography and voltammetry). Consequently, as demonstrated in eqn [2], the measurement of current in amperometry offers a simple and reliable approach for the monitoring of the changes in concentration of the electroactive species that occur during a titration. The main requirement in such a measurement is that at least one of the substances (reactant or product) involved in the titration is electroactive. This ensures that the current flow during the titration is due to either the oxidation or reduction of the reactant or product. Thus, the plot of the resulting current from the titration against the titrant volume will enable the location of the equivalence point. The observed current changes during such a titration is proportional, as suggested by eqn [2], to changes in the concentration of the electroactive species. **Figure 2** shows that the titration curves usually consist of two straight lines and their point of intersection gives the equivalence point.

The method described above is known as 'amperometric titration' and it is widely used in analytical chemistry. Such titrations can be performed in two ways: (1) by adjusting the potential of a single microelectrode within the range of the limiting current of the electroactive species, as in polarography, and subsequently recording the current flow as a function of increasing titrant volume; and (2) by applying a fixed potential to the indicator electrode (i.e., holding the potential difference between a pair of microelectrodes constant), while the current is measured as a function of the titrant volume. The mode in which such a titration is performed can involve either the use of one or two indicator electrode(s), depending on the nature of the titration. These possibilities give amperometric titration an excellent and unique flexibility that, in some cases,

**Figure 2** Amperometric titration curves for systems where (A) only analyte is reduced; (B) only the reagent is reduced; and (C) both analyte and reagent are reduced.

enables the monitoring of the reactive product or reagent, rather than of the analyte.

### Instrumentation

A simple two-electrode electrochemical cell consisting of either single or dual polarizable electrode(s) is normally required for amperometric titrations of various organic and inorganic substances. By definition, a polarizable electrode is a suitable electronic conductor whose potential changes even with the passage of relatively small current. In contrast, the potential of a nonpolarizable electrode, such as the saturated calomel and silver – silver chloride electrodes that are commonly employed as reference electrodes, remains reasonably constant even when a large current is passed.

Amperometric titrations with single polarizable electrodes are based on earlier work that evolve from the use of polarographic techniques. Most of these involved the application of a constant potential to a dropping mercury electrode (DME) and the subsequent monitoring of the current changes as a function of the titrant volume. In cases where the electroactive species are oxidized at potentials beyond the anodic potential range of mercury, a rotating platinum electrode (RPE) may be employed instead of the DME. **Figure 3** illustrates the anodic and cathodic potential limits for mercury and platinum microelectrodes. As can be seen, the use of mercury microelectrodes is limited in the positive (anodic) potential region by the oxidation of water at  $\sim +0.25$  V versus the SCE and in the negative region by the liberation of hydrogen at  $\sim -1.8$  V in acid or  $\sim -2.3$  V in basic media. In contrast, the use of platinum microelectrodes is limited at  $\sim +0.65$  and  $\sim -0.45$  V versus the SCE by the oxidation of water and hydrogen liberation, respectively. Evidently, mercury microelectrodes offer a more substantially negative potential limit for the reduction of electroactive species, whilst platinum microelectrodes permit oxidation at a more positive potential than can be accomplished with mercury microelectrodes.

An RPE can be more easily constructed by using a length of platinum wire sealed in a glass tube and mounted on a synchronous motor to permit rotation at a constant speed. The rotation of the electrode reduces the thickness of the diffusion layer and improves the current densities by a factor of 20–30 times over those obtained with a DME. Despite the higher sensitivity attainable with the RPE, the shape of the amperogram is often similar for both electrodes. However, the magnitude of the measured current with the RPE is sensitive to changes on the electrode surface and, hence, it is more variable from one titration to the other than with a DME. Also, unlike with DME, there is little or no charging current associated with the use of RPE.

The removal of oxygen from solution is almost always mandatory when a DME is employed for amperometric titration, as this substance can be readily reduced on this electrode. In contrast, this does not usually create a problem when an RPE is used for such a titration and therefore it is often possible to use a simple open cell for the titration. In cases where oxygen is a problem, this can be overcome by bubbling nitrogen or argon through the sample solution for 5–20 min and over the solution during the titration.

The choice of titrant concentration is another important consideration in amperometric titration. Substantial dilution of the titrant may result in a

**Figure 3** Attainable anodic and cathodic potential limits for platinum and mercury microelectrodes. (Reproduced with permission from Ewing GW (1985) *Instrumental Methods of Chemical Analysis*, 5th edn., p. 290. New York: McGraw-Hill.)

nonlinear variation of the resulting current, before and after equivalence point, with the titrant volume. The curvature of the straight-line portions of the curve can be corrected by multiplying each current reading by a factor  $(V_1 + V_2)/V_1$ . Prior to the equivalence point,  $V_1$  is the initial volume of the sample and  $V_2$  is the titrant volume. After equivalence,  $V_1$  is the equivalence point volume and  $V_2$  is the titrant volume added beyond the equivalence point. The effect of dilution can be reduced or eliminated by using more concentrated titrant.

Apart from the selection of an appropriate electrode material and titrant concentration, the main requirement in amperometric titration is the choice of either a single or dual polarizable electrode system. The basic differences and characteristics of these two titration systems are discussed below.

#### Titration with a Single Polarizable Electrode

Amperometric titration with a single polarizable electrode utilizes an indicator electrode (polarizable) and a nonpolarizable electrode in the form of a simple working-reference electrode system in which the potential of the former (working/indicator electrode) is held constant relative to the latter (nonpolarizable electrode). As previously illustrated in **Figure 2**, the current flowing due to the oxidation or reduction of the electroactive species in such a system is recorded as a function of titrant volume. For a precipitation titration in which the current flow is caused by the reduction of the electroactive species, increasing addition of the titrant results in the precipitation of the analyte as an insoluble substance and, subsequently, in a decrease in the current flow. **Figure 2A** shows that the current for such a titration will drop to zero and thereafter remain unchanged even when excess titrant is added. The equivalence point for such a titration is determined by drawing the two straight

lines and extrapolating to the intersection to locate the end point. In contrast, **Figure 2B** shows the titration curve for a system in which the titrant is reducible, but the analyte is unreactive. In this case, the potential of the electrode is held at a value where only the electroactive species can be reduced. **Figure 2C** illustrates a titration curve for a system in which both the analyte and the titrant are reducible within the same potential range. In other cases where the electroactive titrant may undergo oxidation at an RPE, the direction of the titration curve will be opposite to that shown in **Figure 2B** and, hence, the resulting current beyond the equivalence point will decrease.

#### Titration with Dual Polarizable Electrodes

This type of amperometric titration utilizes two identical polarizable (indicator) electrodes, in the form of a two working (working-working) electrode system with no reference electrode. A constant potential difference of 10–500 mV is maintained between the two electrodes, but the potential of each electrode may change during the titration and may be outside the limiting current region for the electroactive species. However, under controlled experimental conditions a plot of the resulting current versus titrant volume gives the equivalence point by an abrupt current change, as illustrated in **Figure 4**. Titrations with dual polarizable electrodes are often used for equivalence point detection in redox titration, where one of the electrodes functions as a cathode and the other as an anode.

#### Potential Sources

The polarizable and nonpolarizable electrodes may be connected to a potential source such as a power supply or a potentiostat, and the resulting current from the titration may be recorded with the aid of a

**Figure 4** Amperometric titration curves for redox reactions on dual polarizable electrodes: (A) reversible half-reactions for titrant and sample; (B) reversible half-reaction for sample only; and (C) reversible half-reaction for titrant only. e.p., equivalent point (Reprinted with permission from Peters GD, Hayes JM, and Hieftje GM (1974) *Chemical Separations and Measurements*; © Brooks/Cole, a division of Thomson Learning; www.thomson-rights.com. fax: 800 730-2215.)

microammeter or a damped galvanometer connected in series with the cell.

## Applications

The use of amperometry as an endpoint detection method has been widely adopted for the titration of substances at the millimole per liter level, with excellent analytical precision ( $\pm 1\%$  RSD at  $0.01 \text{ mmol l}^{-1}$  level). The majority of these titrations involve the formation of precipitates, while others involve complexometric and redox titrations. At the millimole per liter level, the accuracy of this method is better than that achievable with other electroanalytical methods and as good as those of spectrophotometric titration.

Amperometric titrations have been more widely applied for the titration of inorganic and organic substances. The titration of inorganic substances usually involves the determination of various anions, cations, or compounds and may involve the formation of precipitates, complexation, or redox reactions of the titrant or the analyte, or both. In this case the analyte, titrant, or both can be electroinactive, and hence can demonstrate all the features of the amperograms shown in Figure 2. Table 1 provides a list of some inorganic substances that can be determined by amperometric titration. Other inorganic substances that can be determined by amperometric titrations include boron, bismuth, calcium, cadmium, copper, hafnium, holmium, indium, magnesium, neodymium, nickel, scandium, samarium, terbium, thorium, thallium, tungsten, zinc bromide, fluoride, hyponitrite, iodate, sulfate, sulfite, and thiosulfate.

In contrast, the amperometric titration of organic substances usually involves the use of an electroreducible titrant in which the organic compound is often unreactive. The flow of current in such a system remains essentially at zero until the equivalence point is

reached, after which the current increases linearly due to the reduction of the excess titrant. Even in cases where both the titrant and titration product are electroactive, the potential can be adjusted to enable the reduction of only the titrant. Table 1 also provides a list of some organic substances that can be determined by amperometric titrations. Other organic substances that can be determined by amperometric titrations include aromatic amines, aromatic nitrosocompounds, ascorbic acid, benzotriazole, cysteine, dithiocarbamates, dodecylammonium bromide, dodecylpyridinium bromide, ethylenediaminetetraacetic acid (EDTA), formaldehyde, hydroxylamine salts, hydroquinone, ketones, thiazoles, organic mercapto groups, opium, salicylates, quaternary ammonium salts, sulfanilamide, alkaloids, sulfenamides, isothiocyanates, urea, and other amides.

## Chlorine in Water and Wastewater

Amperometric titrations have been successfully used for accurate determination of residual chlorine in water. Different species of chlorine have also been determined, with suitable modification of the method, as free available chlorine, chloramine, chlorine dioxide, and chlorite. Various dual polarizable electrodes have been used for the amperometric titration of low concentrations of residual chlorine in water. In particular, amperometric (iodometric) titrations with dual platinum electrodes have gained considerable interest in the determination of total residual chlorine in water. Selective iodometric titrations with dual polarizable electrodes have also been found to be useful for the speciation of chlorine in water, providing the ability to distinguish between free and combined residual chlorine, and between monochloramine and dichloramine in water. For example, in the absence of iodide only the residual chlorine is detected at the neutral pH range in water and, hence, with the addition of iodide at this pH range monochloramine can also be detected. Consequently, by bringing the pH down to 4 and adding more iodide, dichloramine can be detected as well. To obtain the free available chlorine concentration, chlorine dioxide must be removed by hydrolysis at a high pH prior to the titration of the neutral sample solution in the absence of iodide. If not removed, chlorine dioxide is reduced by iodide to chlorite quantitatively and 20% of this contributes to the concentrations obtained for free available chlorine and chloramine. The chlorite generated from the reduction of chlorine dioxide by iodide can be reduced quantitatively to chloride in acid solution and, hence, subsequent titration in neutral solution will measure chlorite, chlorine dioxide, free available chlorine, and chloramines. The presence of nitrogen trichloride has been found to

**Table 1** Analytical applications of amperometric titrations

<i>Sample</i>	<i>Analyte</i>	<i>Reagent/titrant</i>	<i>Polarizable electrode</i>
Insecticides	Total chlorine	Silver nitrate (after decomposition with Na and xylene)	Sliver
Water–petroleum refining	Chloride	Isoamyl alcohol–ethanol	RPE
Water	Arsenic	Potassium bromate	RPE
	Chloride	Silver ion	Graphite or RPE
Serum	Chloride	Silver ion	Graphite
Plating baths	Thiourea	Mercuric nitrate	Mercury
Spent sulfite liquor	Total sulfur	Lead nitrate (after oxidation to sulfate)	RPE
Catalysts	Palladium	Potassium hexacyanoferrate	RPE
		Potassium thiocyanate	Platinum
	Platinum	Cerium(IV)	Graphite or RPE
		Sodium thiosulfate after treatment with KI	RPE
Drugs	Aluminum	EDTA	RPE
Quartz glasses/glass	Vanadium	Glycinethymol blue	RPE
		EDTA	Rotating
			Graphite
Nuclear fuels	Uranium	Mohr's salt	RPE
Iron ores	Iron	Manganese(III)	RPE
Ores	Mercury	Thiosalicylic acid	RPE
Steels	Cobalt	Potassium hexacyanoferrate in ammoniacal medium	RPE
	Phosphorus	Conversion to molybdophosphate followed by the titration of Mo	Graphite or RPE
	Vanadium	Ferrocene	Graphite or RPE
		Copper(I)	RPE
		Mohr's salt	RPE
	Vanadate	Potassium iodide	RPE
		Naphthylamine	RPE
	Chromate	Potassium iodide	RPE
		Naphthylamine	RPE
	Chromium	Copper(I)	RPE
		Calcium caboxymethyldithiocarbamate	
	Manganese	Copper(I)	RPE

contribute mainly to the free chlorine fraction and partially to the chloramine fraction. In these titrations, the endpoint is indicated by a decrease in the current to zero. The sample must be stirred thoroughly during the titration and the entrainment of air by cavitation must be avoided.

The presence of other oxidizing agents such as manganese(IV) can interfere with the chlorine determination if the titration is performed at  $\text{pH} < 3.5$ . Under this condition, the organic chloramines are often converted to either monochloramine or dichloramine, resulting in positive errors for these substances. Also, the volatilization of chlorine compounds can result in low recoveries. This can occur due to the violent agitation or aeration of some of the chloramines prior to the addition of iodide.

These losses can be avoided by using two portions of the sample: one for the determination of the free chlorine and the other treated with the titrant and iodide prior to the determination of the chloramines. Ferric and chlorate ions do not interfere, while nitrites and manganese dioxide are present only as chlorites.

As the residual chlorine in wastewater is usually combined, iodide is often added to liberate iodine, which is more active than the combined chlorine. Such liberation is necessary in view of the presence of amines, ammonia, organic nitrogen, and other organic compounds in wastewaters that tend to combine with a large proportion of the free residual chlorine. The losses of the liberated iodine at  $\text{pH} \leq 4$  are relatively small, but it is preferable to add excess

titrant before adding iodide and consequently back-titrating with standard iodine. This often involves the mixing of the standard titrant (potassium iodide) and the buffer, prior to adding the sample and subsequently titrating with a standard iodine solution. The use of a titrant, such as sodium arsenite, at this low pH is not possible and therefore either phenylarsine oxide or sodium thiosulfate is often employed. The use of phenylarsine oxide as a titrant is preferred over others due to its much higher stability. When employed as a titrant, the interferences from other oxidizing agents, such as manganese(IV), is avoided by performing the titration at pH 3.5. Chromate, silver, and cuprous ions are known to interfere with the amperometric titration of chlorine in wastewater. Also, this method cannot be performed in the presence of high concentrations of cupric ions. Problems with color and turbidity are easily avoided by the use of amperometric endpoint instead of the starch endpoint approach. Chlorine dioxide can interfere with the amperometric titration of both the free residual and combined chlorine. In cases where the organic chloramines react very slowly at  $\text{pH} \geq 3.5$ , the use of lower pH (1.0–2.5) is recommended.

The amperometric titrations of chlorine in water and wastewater are particularly useful in establishing the correlation between the degree of disinfection and residual chlorine. This titration is also often used as a standard method of comparison for the determination of free or combined chlorine. It is relatively more sensitive and has a detection limit of  $0.01 \text{ mg l}^{-1}$ , which is superior to the limit of  $\geq 1 \text{ mg l}^{-1}$  achievable by most colorimetric and titrimetric methods. Furthermore, the amperometric determination of chlorine is less affected by common oxidizing agents, color, turbidity, and temperature variations. However, the skill and care required for reliable amperometric titration is much higher than that required for other methods.

### Total Oxygen Demand

Two of the most useful parameters in the assessment of water quality are biochemical oxygen demand (BOD) and chemical oxygen demand (COD). Unfortunately, the measurement of these parameters is time consuming and suffers from some interferences. The BOD method requires a 5-day incubation period, while the COD measurement requires a complex decomposition of the sample solution.

An alternative method known as total oxygen demand (TOD) is based on the use of amperometry. It involves the passage of a carrier gas containing a small, but constant amount of oxygen through a heated tube containing a catalyst and then into a

galvanic type cell that consists of a silver cathode and a lead anode, covered with a layer of potassium hydroxide. After attaining a steady-state current, a small aliquot (20  $\mu\text{l}$ ) of water sample is injected into the carrier gas. Consequently, the oxidizable substances in the water react with oxygen in the catalyst furnace, resulting in an oxygen depletion that is detected amperometrically by a decrease in the current. TOD results often agree favorably with COD values when the latter are not affected by interferences. Each TOD measurement takes  $\sim 3$  min and is amenable to remote and/or intermittent monitoring by the use of an appropriate sample injection device.

### Total Available Heavy Metals

A square-wave amperometric titration has been used for the determination of the total available heavy metals in water samples. This method involves the direct anodic oxidation of mercury in the presence of excess EDTA. The resulting mercury wave is used to detect the endpoint of the amperometric titration by running a polarogram after each successive addition of an aliquot of EDTA. The successful utilization of this method lies in the ability to discriminate between  $\text{Ca(II)}$  and heavy metals, such as  $\text{Cu(II)}$  and  $\text{Zn(II)}$ . Thus, in practice, it involves 1:1 dilution of samples with  $0.2 \text{ mol l}^{-1}$  acetate buffer (pH 4.8), prior to the amperometric titration. At this pH, heavy metals, such as  $\text{Fe(III)}$ ,  $\text{Hg(II)}$ ,  $\text{Ni(II)}$ ,  $\text{Cu(II)}$ ,  $\text{Pb(II)}$ ,  $\text{Zn(II)}$ ,  $\text{Cd(II)}$ ,  $\text{Co(II)}$ , and  $\text{Al(III)}$ , are completely ( $\geq 99\%$ ) converted to EDTA complexes. Furthermore, the presence of  $\text{Ca(II)}$  does not interfere with the determination of the available heavy metals under these conditions. As little as  $1 \mu\text{mol l}^{-1}$  of available heavy metals has been successfully determined in water samples by this method.

## Amperometric Sensors

### Origin

Unlike other sensors, most of the available chemical amperometric sensors evolved from earlier investigation of various electrochemical processes on electrode surfaces, long before the use of the generic term of 'chemical sensor' became acceptable. Of course, as the emphasis of such earlier work was directed mainly toward the prediction and understanding of electrode mechanisms rather than for analytical purposes, most of these investigations were done under conditions that were not fully comparable with a modern sensing device. However, the considerable knowledge gained from the earlier work has been most beneficial in the design and development of amperometric sensors. This has led to the

development of reliable amperometric sensors for oxygen and chlorine, as well as to the development of biochemical sensors for various substances.

### Dissolved Oxygen Sensor

By far the most important application of amperometry is the determination of dissolved oxygen. An earlier approach for oxygen measurement made use of the galvanic type cell, which consists of a zinc anode and a carbon, gold or platinum cathode, and hence does not require the application of an external polarizing potential. Unfortunately, this cell arrangement was prone to poisoning when used in direct contact with samples containing surface-active substances and/or suspended solids. The prevention of the accumulation of deleterious substances on the electrode surfaces was achieved by covering them with a membrane. As well as keeping the electrode clean, the membrane establishes a finite diffusion layer that stabilizes the electrode performance. In effect, the membrane-covered electrodes become independent of the hydrodynamic properties of the sample solution.

The main requirement in the use of membranes in the construction of oxygen sensors is that the membrane must be permeable to oxygen, while restricting the passage of water and electrolyte. On this basis, the use of a single point calibration method based on the use of air, with the assumed linearity of response for other measurement, is feasible. Another calibration method involves the use of solutions previously verified by the Winkler oxygen titrimetric method.

One oxygen sensor design utilizes a concentrically mounted cathode and anode embedded in a plastic material, with only the surfaces of the electrodes exposed to the sample solution. In operation, a thin layer of the supporting electrolyte, such as potassium chloride or potassium hydroxide, is brought in contact with the electrodes by confinement within the outer membrane. The dissolved oxygen, which diffuses through the membrane, undergoes electrochemical reduction at the cathode within the confined layer. The resulting current from the reduction process is directly proportional to the oxygen concentration in solution.

Another galvanic oxygen sensor utilizes a lead anode, a silver cathode, and  $4\text{ mol l}^{-1}$  potassium hydroxide as electrolyte. In addition, a microammeter is connected in between the anode and cathode to provide the current readings. The flow of current, as in other oxygen sensors, is due to the diffusion of oxygen from the sample solution through the membrane to the silver cathode, where it is reduced:

**Figure 5** A galvanic oxygen sensor. The electrolyte is  $4\text{ mol l}^{-1}$  potassium hydroxide.

and the lead anode is subsequently oxidized in the presence of the hydroxide:

Figure 5 illustrates a typical cell arrangement for a galvanic oxygen sensor. The electrodes are insulated from each other with nonconducting plastic and the surface is covered with a permeable membrane. In practice, a few drops of the electrolyte is added between the membrane and the electrodes. The amount of oxygen that travels through the membrane is proportional to the dissolved oxygen concentration in the sample. The main requirement in using this sensor is to construct and calibrate the meter in such a way that the resulting current can be directly related to the oxygen concentration in sample solutions.

There are also nongalvanic oxygen sensors that are based on the same principles. This type of oxygen sensor typically consists of an inert metallic cathode covered with a gas-permeable membrane and a silver anode. These sensors are usually connected in series with a 1.5 V battery and an external potential of 0.8 V is applied between the electrodes to initiate the amperometric measurement of oxygen. One such sensor employs a gold cathode, a silver anode, and a potassium chloride gel as the electrolyte.

Owing to the realization in the 1970s that the current of a microelectrode ( $< 10\text{ }\mu\text{m}$ ) rapidly reaches a steady-state value that is not sensitive to mass transport, there has also been some considerable interest in developing microelectrode-based oxygen sensors. The construction and utilization of a microelectrode-based Clark-type oxygen sensor has gained wider use in the past two decades. In addition, the incorporation of such a micro-oxygen sensor on a chip for the multiampereometric sensing of oxygen and other substances, such as glucose and glutamate, with the aid of immobilized enzyme layers has been reported. Also, miniaturized oxygen sensors, placed either on the tip of a catheter or mounted in a microcell through which the sample is pumped or stirred into, are commonly used in clinical studies.

The available amperometric oxygen sensors are capable of determining dissolved oxygen concentration in aqueous media reliably when present between 0.1 and 50.0 mg l<sup>-1</sup> and they are readily amenable to field studies. Due to the membrane coverage of the electrodes, the sensors can be readily used in solutions containing both ionic and organic contaminants, as well as in gaseous environments. When used for the determination of oxygen in blood and other biological fluids, the covering membrane has also been found to be useful in preventing contamination and fouling by other blood constituents, such as erythrocytes. Potential interferences include sulfur dioxide, hydrogen sulfide, and other gaseous substances that can permeate the outer membrane.

A DME has also been used for the amperometric determination of oxygen in river water and effluent samples. This involves the application of a constant potential of -1.5 V versus the SCE. This approach has been found to be useful in eliminating interferences from cyanide and sulfide, as well as correcting for contributions from metal ions, such as iron, copper, zinc, and nickel. The method can be reliably used for oxygen determination when present within the concentration range of 0–15 mg l<sup>-1</sup>.

The various oxygen sensors have not only gained wider use in laboratory and in-field analysis, they have also become popular for online monitoring of industrial processes.

### Chlorine Sensor

Amperometric sensors, of similar design to the oxygen sensors, are also available for chlorine determination in water and wastewaters. In this case, the sensor employs a silver wire cathode, immersed in a sodium chloride solution in the inner tube, and a platinum wire anode wound around a porous thimble on a glass tube. The electrode assembly, which functions as a galvanic cell, is employed in a similar approach to the dissolved oxygen probe, giving a current reading upon immersion into sample solution. The resulting current is also directly proportional to the concentration of the active chlorine in the sample. This type of sensor has gained considerable use for domestic and industrial purposes.

### Biosensors

The immobilization of enzymes, cell cultures, tissues, and other biologically active substances on various electrode substrates have been explored extensively for the development of amperometric biosensors for various substances. This approach has been useful in improving the selectivity of amperometric measurements and hence for developing new amperometric

biosensors. Earlier work in this area concentrated on the construction of enzyme electrodes that employ oxygen sensors as transducers. The most well known and widely used enzyme electrode is the glucose electrode, which has even been used as an implantable sensor in clinical studies/monitoring. Several other transducers that are not based on the use of oxygen sensors are now widely used in this area and many new amperometric biosensors are reported regularly in the literature.

### Amperometric Detectors for Chromatography and Flow Injection Analysis

Two other areas where amperometry has played a major role since the 1970s are the detection of various substances in high-performance liquid chromatography and flow injection analysis. To a lesser extent, amperometric detection has also been applied to ion chromatography of anions and cations.

## Introduction

Amphetamines and related compounds have a long and storied history extending literally thousands of years in the past with the use of the drug 'Ma Huang' in China (identified as ephedrine in the late 1800s). Amphetamine is a synthetic drug first produced in 1887 followed several years later by methamphetamine in 1914 (structures given in **Figure 1**). The simple nature of these molecules is deceptive when compared with the numerous and varied activities they have within the body. Their central nervous system (CNS) activity is that of an indirect acting sympathomimetic and it is their CNS stimulatory activity that leads to their potential for abuse. In addition to their CNS activity, amphetamines also have peripheral activity. Their site of action is dependent

on the enantiomeric form of the drug present with the (*S*)-enantiomer having the greatest CNS activity. Several of the drugs in this class are on the schedule of controlled substances while others are commonly found in over-the-counter medications. Clinically, amphetamine and methamphetamine are used for treatment of narcolepsy, attention deficit disorder with hyperactivity, and as an anorexic. Tolerance and dependence can rapidly develop therefore leading to strict prescribing guidelines.

Following administration of methamphetamine, both methamphetamine and amphetamine are excreted. The excretion profile of these drugs is dependent on both metabolism and excretion; the longer the drugs remain in the body, the more metabolic degradation takes place. The 'average' excretion of unchanged drug is ~30% for amphetamine and 43% for methamphetamine. The actual amount of unchanged amphetamine excreted in urine is greatly affected by pH and can vary from as little as 1% in highly alkaline urine to as much as 74% in strongly acidic urine. Methamphetamine also shows widely differing excretion rates that range from 2% in alkaline urine to 76% in acidic urine. The amount of methamphetamine excreted in the form of amphetamine also varies from 7% in acidic urine to as low as 0.1% in strongly alkaline urine reflecting the metabolism of methamphetamine and amphetamine as long as the drug remains in the body. Methamphetamine is demethylated to amphetamine and subsequently to a number of different compounds prior to excretion. The metabolic pathways of amphetamine and methamphetamine are summarized in **Figure 2**.

Here, the use of amphetamines, common analytical methods used in their analysis, their analysis in various biological fluids, and the unique aspects related to forensic analysis of amphetamines are reviewed. A glimpse at the future trends in analysis of the amphetamines is also provided.

## Methods

Analysis of amphetamines is commonly accomplished using a number of different methodologies. These include techniques such as thin-layer chromatography (TLC), gas chromatography (GC), liquid chromatography (LC), infrared spectroscopy, and mass spectrometry (MS). In addition, several different immunoassays are commonly used for the analysis of amphetamines.

**Figure 1** Structures of stereoisomer of amphetamine and methamphetamine. Note: The references to the stereoisomer of amphetamine and methamphetamine are often designated using various different indications of the orientation. Common designations for the dextro form of the drugs include *d*, *d*, *D*, *S*, and (+) and similarly for the levo form the designations *l*, *l*, *L*, *R*, and (–) are used.

**Figure 2** Structures of major metabolites of amphetamine and methamphetamine. 1, Methamphetamine; 2, amphetamine; 3, hydroxymethamphetamine; 4, hydroxyamphetamine; 5, hydroxynorephedrine; 6, norephedrine; 7, phenylacetone; 8, benzoic acid; 9, glycine; 10, hippuric acid. Note: stereochemistry and ionic state are not indicated in these structures and conjugates, other than hippuric acid, are not shown.

All immunoassays are based on the principle of competitive displacement of a labeled drug from an antigen–antibody complex by unlabeled drug in the sample. The fundamental difference in the currently available immunoassays is the

detection method employed. Commonly used methods include: fluorescence polarization, enzyme immunoassay, cloned enzyme donor immunoassay, enzyme-linked immunosorbent assay, and radioimmunoassay.

In all of the immunoassay methods, the antibodies are targeted to the amphetamines of interest and designed to minimize cross-reactivity with related compounds. While seemingly simple, achieving specificity is a significant challenge. Since there are so many compounds found in biological fluids that are structurally similar to the amphetamines, specificity is difficult to attain. Tremendous advances have been made over the past several years in this area, however, and the newer assay systems are far better at properly identifying the presence of amphetamine and methamphetamine while significantly diminishing cross-reactivity to related compounds. An advantage of immunoassays over other methods is they are rapid and require no sample preparation. A sample can be added directly to the reagents and the presence of the drugs determined in a relatively short time. Immunoassays are the most popular screening method because they lend themselves to automation thus allowing laboratories to process large numbers of samples. Their biggest disadvantage, however, is lack of specificity. Quantification based on immunoassay is possible, but owing to differing binding affinities to substances, including metabolites, the accuracy of this approach is generally limited. The most common application of immunoassays is as a screening tool for the identification of presumptive positives that are then confirmed by another more specific confirmation assay.

TLC is more specific in the identification of amphetamines but is a far more time-consuming procedure than are immunoassays. With few exceptions, in order to analyze a sample by methods other than immunoassay, the drugs are extracted from the biological matrix prior to analysis (see later). In the case of TLC, the development (chromatographing the drugs up the plate) is a relatively slow process that adds to the time required for analysis. TLC does have the advantage of being able to identify a wide variety of compounds in a sample and is not limited to testing for a single compound or class of compounds as are the immunoassays. Because of the structural similarities, separation of the amphetamines from the many different closely related amines is often not possible with a single solvent system. Typically, using a number of different solvent systems does allow for separation and identification of the individual compounds. Another disadvantage of TLC is it does not have the sensitivity of the other methods. Quantification using TLC is possible only with substantial effort; therefore, it is typically used only as a qualitative tool although some high-performance thin-layer chromatography methods have been shown to be quite specific and precise.

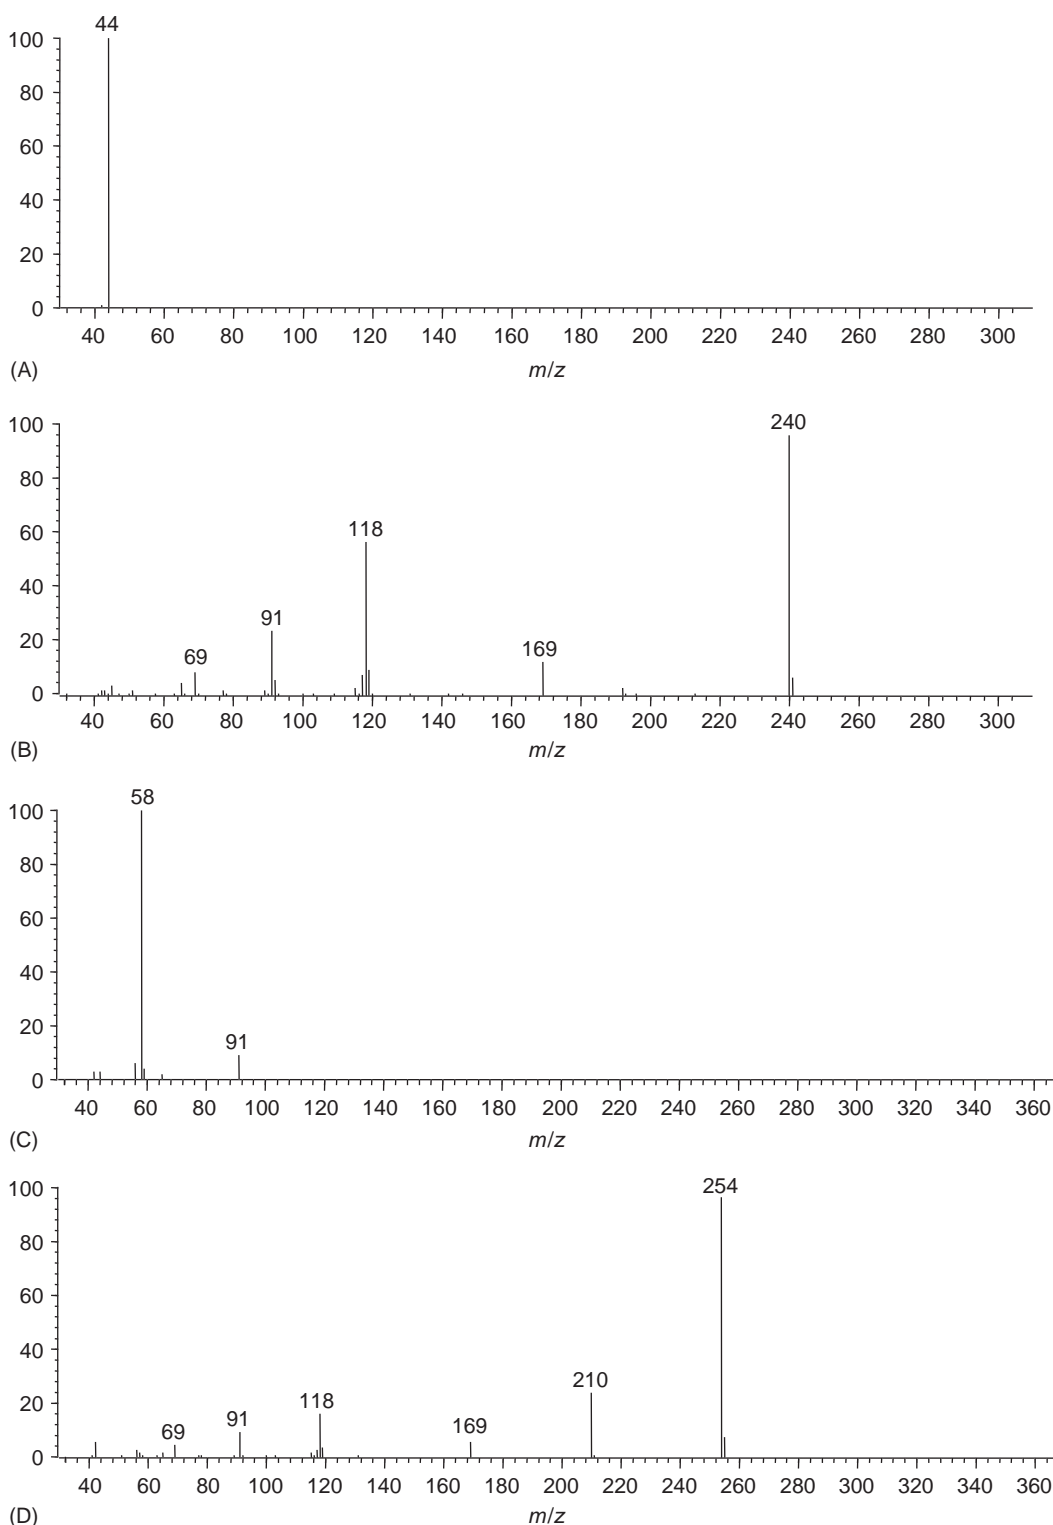

LC is a powerful analytical tool and has been used for the identification of amphetamines in virtually all biological samples. The resolving power of LC allows for specific identification of the drugs and often requires less sample preparation than other chromatographic methods. The natural ultraviolet absorbance of the amphetamines allows for identification by LC, and if derivatized, fluorescent and electrochemical detectors yield even more sensitive and specific detection of these drugs. Derivatization of the amphetamines also enhances their chromatographic behavior. Use of appropriate chiral stationary phases or chiral derivatizing reagents also allows chromatographic separation of the enantiomeric forms of amphetamine and methamphetamine.

Typically, GC has even greater sensitivity than LC and is used with a number of different detectors including flame ionization (FID), nitrogen-phosphorus (NPD), electron capture (EC), and MS. The FID is essentially a universal detector because virtually any flammable compound generates a response.

The NPD, as the name implies, is sensitive for compounds containing nitrogen. It therefore works well with amphetamines because of the presence of the amine group. This detector is also a selective technique owing to the specificity of detecting only those compounds containing nitrogen or phosphorus, thus eliminating many potentially interfering compounds in the sample extract. Electron capture is also a very sensitive detection technique that has been effectively used for amphetamines. However, unlike the NPD, EC detection requires derivatization of the amphetamine with a strongly electronegative group such as a perfluoroacyl group prior to analysis.

Mass spectrometers are commonly used in combination with a gas chromatograph. Most GC-MS analysis of amphetamines is accomplished in the electron ionization mode. This is typically because of the wider availability and ease of use of this ionization method. Chemical ionization is also used for analysis of amphetamines, taking advantage of the relatively high ionization efficiency of the amphetamines when using a reagent gas such as ammonia. A disadvantage of using chemical ionization, however, is the higher degree of complexity in using the instrument and the lessened degree of characteristic fragmentation when compared with electron ionization of derivatized amphetamines.

Derivatization of the amphetamines is not required for GC-MS analysis. However, because the mass spectra of underivatized amphetamines are very simple and essentially composed of ions at  $m/z$  44 for amphetamine and  $m/z$  58 for methamphetamine, derivatization is used to not only yield higher mass ions but also to provide multiple characteristic ions

**Figure 3** Mass spectra of (A) amphetamine, (B) heptafluorobutyryl derivative of amphetamine, (C) methamphetamine, (D) heptafluorobutyryl derivative of methamphetamine.

for unequivocal identification of the analyte. The spectra of underivatized amphetamine and methamphetamine and the spectra of the corresponding heptafluorobutyryl derivatives are illustrated in **Figure 3**.

The gas chromatographic behavior of underivatized amphetamines, which tends to show tailing asymmetrical peaks, is also dramatically improved by derivatization. As is true for LC, appropriate

**Figure 4** Gas chromatography of trifluoroacetyl-(L)-prolyl derivatives of amphetamine and methamphetamine enantiomers. Peaks: A, (*R*)-amphetamine; B, (*S*)-amphetamine; C, (*R*)-methamphetamine; D, (*S*)-methamphetamine. GC conditions: 120°C for 2 min, rising to 200°C at 4°C min<sup>-1</sup>. Ions monitored at *m/z* 237 for amphetamine and *m/z* 251 for methamphetamine.

chiral stationary phases or chiral derivatizing reagents allow chromatographic separation of the enantiomeric forms of amphetamine and methamphetamine by GC. The most common of these methods involves use of trifluoroacetyl-L-prolyl chloride (TPC). On standard achiral GC columns, the enantiomeric forms of amphetamine and methamphetamine co-chromatograph unless derivatized with a chiral reagent such as TPC. When derivatized with a chiral reagent, they can then be readily separated. The gas chromatographic separation of the enantiomers of amphetamine and methamphetamine is shown in Figure 4.

## Sample Preparation

In most analytical procedures, other than immunoassays and a few LC procedures, the amphetamines must be extracted from their biological matrix. There are numerous methods for the extraction of amphetamines from biological samples; the most common include liquid-liquid and solid phase. The *pK* of the amine group on these drugs is ~9.9, thus making the sample alkaline significantly enhances their extraction into organic solvents. Simply by adjusting the sample pH to greater than the *pK*, the amphetamines can be efficiently extracted into a small amount of organic solvent. To provide a cleaner extract, samples are often back-extracted from the organic solvent into an acid solution, leaving the purely lipophilic compounds behind. After adjusting the pH again to a high level, the amphetamines are re-extracted into the organic solvent, yielding a much cleaner extract than is achieved by the single-step extraction.

Solid-phase sorbent materials used for the extraction of amphetamines allow for high recovery and selectivity. Binding the amphetamines to the column packing material allows for washing away of the

unwanted components in the sample. Several column sorbents can be used for extraction including those based simply on hydrophobic interactions such as C<sub>18</sub>. These use the hydrophobic interactions between the drugs and the sorbent to extract the compounds of interest. In the case of the amphetamines, this requires adjustment of the pH to a level that can cause problems with silica-based columns. Another method is to use ion exchange where the sample pH is slightly acidic (commonly 6.0) leaving the amine group positively charged. The ionic interaction between the analyte and the column is quite strong allowing the use of strong wash solvents to eliminate potentially interfering compounds. The drugs are then eluted by increasing the pH causing the loss of charge and therefore strong interaction with the column. Due to their versatility, the most popular columns are actually bifunctional in that they contain both ionic and hydrophobic binding capabilities. Such columns can therefore be used to eliminate more potentially interfering compounds in the sample than liquid-liquid extraction or single-mode solid-phase extraction and generally have the potential to produce a cleaner extract.

Protein precipitation is common prior to extraction of drugs from blood samples. Whole blood can also cause problems with solid-phase extraction by plugging the column, although these difficulties can be overcome by precipitation or dilution. Although both liquid-liquid and solid-phase extractions give excellent recoveries of amphetamine and methamphetamine, other closely related compounds are often extracted under the same conditions. In some cases, the initial concentrations of these compounds are so high that, even if their recovery is relatively low, they can pose significant problems in the analysis. One method of eliminating this interference is to destroy the unwanted compounds using an oxidizing agent such as periodate. Hydroxylated compounds such as ephedrine, pseudoephedrine, and phenylpropanolamine are oxidatively cleaved by periodate oxidation, thus they do not interfere with the assay.

## Biological Samples

Urine is the most commonly used biological fluid for the analysis of amphetamines. Blood is also often used for this purpose and the choice of specimen is, to a large extent, dictated by the purpose of the analysis. Other biological samples used in the post-mortem setting include vitreous humor and various tissue homogenates. When testing workplace or sports testing samples, urine holds a variety of advantages over blood. The most obvious is that urine collection is physically less intrusive than

collecting blood samples. In addition, detection of amphetamine use is easier in urine for a number of reasons, including higher concentration of the drugs and extended detection times compared with those in blood. As with all urine drug testing, however, the measured concentration of the drug in urine does not correlate well with the activity of the drug on the body at the time of collection. While interpretation of urine drug testing data is limited, it is further hampered in the case of amphetamines by the fact that the excretion rate is greatly affected by the urinary pH. The differences in the rates of excretion can yield half-lives from 7 to 34 h for amphetamine and from 12 to 34 h for methamphetamine. An advantage of measuring drug concentrations in blood is that it allows the determination of the amount of the drug available to various tissues. However, the interpretation of the total dose of a drug or time since dose is complicated by the fact that blood levels are also significantly influenced by the variable excretion rates of the drug. Since blood concentration represents the amount of drug available in the body at the time of collection, the level can be helpful in determining the influence, if any, the drug had on the individual at that time. From a clinical viewpoint, these questions are often less important than in a forensic investigation.

The use of hair as a sample for detection of drug has been used for a number of years. Hair has the advantage of serving as a record of past drug use. Since drugs deposited in hair are placed there shortly following use, as the hair grows, it represents a sequential history of use over time. Deposition of drugs into hair has been investigated and several important studies have shown the specific drugs and drug metabolites incorporated into hair after use. Issues of differences in hair composition and external contamination have to be considered when analyzing hair and extensive protocols have been developed to ensure the drug detected was actually incorporated into the hair rather than being contamination by environmental contact. A significant challenge with analysis of drugs in hair samples is the low levels found compared to those seen in other biological samples. Modern instrumental methods, particularly MS-MS, have allowed hair analysis to become a more commonly used technique for the detection of drug use. Sweat has also been used as a sample for the detection of drug use. Like hair, sweat can be used to detect use for a longer period of time than the other sample types. Unlike the other samples, however, sweat collection is more time consuming. An absorbent patch is placed on the subject and remains in place for a period of time (commonly a week), then the patch is removed and analyzed for

the presence of drugs. Evaluation of contamination has been conducted and the technique has been shown to identify drug use during the time the patch was in place. Another sample matrix gaining in popularity is oral fluid. Drugs are excreted into the saliva which can be relatively quickly collected and tested. Oral fluid is collected either as an expectorated fluid which is collected into a small sample container or, more commonly, using a device with an absorbent pad that collects the fluid. The pad is then placed in a buffer, allowed to equilibrate, and is then tested for the presence of drugs. This procedure holds some advantages in that the sample collection is less invasive than collection of blood and less intrusive than collection of urine. It also avoids many of the potential problems of sample substitution and adulteration possible, particularly with unobserved collection of urine samples. Several studies have evaluated the extent of drug found in oral fluid following use, but more work needs to be accomplished to fully characterize the details.

## Forensic Samples

Forensic analysis of samples poses challenges not encountered with analysis for research or clinical purposes. Some of the challenges are related to the forensic nature of the analysis itself and sometimes to the fact the sample itself may be far different from those seen in typical analysis (e.g., clotted blood in postmortem analysis or urine that is several days old rather than fresh). Almost any sample can be 'forensic' since the forensic nature of a sample comes from the use to which the analytical result is put rather than from the actual nature of the sample itself. As a result, virtually any biological fluid or tissue may be a forensic sample. One critical component of forensic analysis is the need to document the origin and handling of the sample from collection until analysis is completed, maintaining a clear, well documented 'chain-of-custody'. Urine is the most commonly analyzed sample for amphetamines and the results of that testing are often used as evidence in legal proceedings. Blood is also a good sample for detecting the presence of amphetamines. Since a considerable amount is known about amphetamines in terms of their pharmacology and pharmacokinetics, blood is a more valuable tool in the determination of influence of the amphetamines on an individual. Ante-mortem blood may be analyzed to determine whether or not amphetamines were used and can be important in determining the pharmacological influence of the amphetamines on the individual. This information can be helpful in determining whether the individual was intoxicated or under the influence

of the drugs at the time the sample was collected. Postmortem analysis of blood is also useful in the determination of amphetamines and can be of significant value in interpreting the cause or potential contribution of the drugs to the death. Of particular interest in postmortem analysis is evaluation of the sample for other compounds that may interact with amphetamines to produce a potentially lethal combination where neither compound by itself would have caused the effect. Another complication in postmortem analysis is redistribution of drugs after death which complicates interpretation.

Interpretation of analytical results is a critical part of forensic analyses. Owing to the complex nature of the pharmacokinetics of the amphetamines, interpretation can often be quite difficult. A critical issue in forensic analysis is to separate legitimate use of drugs from illicit use. Another issue, particularly in postmortem analysis, is showing the effect of the drug on the body even if used with valid medical prescription. Several factors make the interpretation of amphetamine results problematic. One of these is the formulation of the Vicks Inhaler in the USA which contains 50 mg of (*R*)-methamphetamine (levmetphetamine). Although this formulation is not found in all parts of the world, it is readily available throughout the USA. This over-the-counter medication is commonly used to treat the nasal congestion associated with colds and allergies due to its peripheral vasoconstrictive effects. Methamphetamine used in prescription medications is (*S*)-methamphetamine and illicit methamphetamine is almost always (*S*)-methamphetamine or racemic (*R,S*)-methamphetamine. In commonly used analytical methods, enantiomers cannot be differentiated from one another. Therefore, use of controlled methamphetamine or the over-the-counter Vicks Inhaler would lead to the same result. However, the use of LC or GC with either chiral columns or a chiral derivatizing reagent will allow the enantiomers to be separated and indicate the difference between use of a Vicks Inhaler and a controlled form of the drug.

Another complicating factor for interpretation of positive test results is the fact that there are a number of other drugs that are metabolized by the body to either amphetamine or methamphetamine. This situation is difficult to determine in many cases because the parent drug is either not excreted or is excreted for only a short period of time in detectable amounts. Drugs that are metabolized to methamphetamine and/or amphetamine include: amphetaminil, benzphetamine, clobenzorex, deprenyl, dimethylamphetamine, ethylamphetamine, famprofazone, fencamine, fenethylline, fenproporex, furfenorex, mefenorex, mesocarb, and prenylamine.

## Emerging Techniques in Amphetamine Analysis

In recent years, a novel extraction technique has been developed and several investigators have implemented this procedure in the analysis of amphetamines. Solid-phase microextraction (SPME) exploits the long-used principle of volatilizing analytes of interest into the headspace over a liquid sample. Headspace analysis has been employed for many years for a variety of volatile compounds, including the amphetamines. The uniqueness of SPME (and a related technique; solid-phase dynamic extraction) is that it allows concentration of the analyte(s) onto the sorbent needle. Following absorption of the analyte(s), the fiber is placed into the injection port of the GC and the compounds are thermally desorbed and analyzed. Modifications of this fundamental technique are to extend the fiber into the liquid itself thus allowing analysis of compounds that are not volatile and can therefore not be collected from the headspace. Several techniques have also been developed to derivatize the extracted analytes. A significant advantage of SPME is the fact that a sample need only be placed into the instrument and no other intervention is required to analyze samples. Currently, the most significant drawback to widespread use of SPME is the time required to analyze each sample.

Analyses of amphetamines, like most other drugs, are most commonly accomplished using GC-MS, which remains the gold standard for confirmation analysis. Concern about the (*R*)-enantiomer has also led to chiral separation techniques being used for definitive analysis of methamphetamine to establish whether or not the drug was an over-the-counter form or a controlled form of the drug.

The coupling of GC-MS with other analytical techniques is being used to assist in the unequivocal identification of amphetamines and various related compounds. One example of this is the use of Fourier transform infrared spectroscopy. The use of multi-stage mass analysis has arrived in the form of mass spectrometers that are capable of doing mass analysis on a compound followed by further fragmentation and analysis in a second mass analysis. Coupling this capability with GC (or LC) has dramatically increased the specificity of analysis and affords greater sensitivity due to the decreased potential for interference and lower background signal. The dramatic advantage of specificity gained by MS over other less specific techniques is dramatically enhanced by tandem mass spectrometry (MS/MS). MS/MS analysis is generally referred to as being accomplished in time or space. MS/MS in space is used to describe MS/MS in the linear triple quadrupole analyzer.

Ionization in the source is accomplished and the first quadrupole is set to isolate a single precursor ion. This ion is then fragmented in the second quadrupole that is filled with a collision gas that causes the ion to fragment. The product ions thus formed can then be scanned or selectively monitored in the third quadrupole.

MS/MS in time is used to describe MS/MS in the ion trap. Basically, MS/MS analysis in the ion trap is accomplished by external ionization of the analytes with the ions then being introduced into the trap. The ion to be used as the precursor is 'trapped' while all others are ejected from the trap. Energy is then added to cause fragmentation of the trapped ion and the resulting product ions are scanned out of the trap and detected.

As described earlier, high-performance liquid chromatography (HPLC) has been used for many years for the analysis of a wide variety of analytes. Numerous different detectors have been used with HPLC. Coupling MS with HPLC dramatically expanded following the development of atmospheric pressure ionization techniques. This was quickly followed by development of benchtop instruments making them less expensive and more widely available to laboratories. The ability to use less extensive extraction procedures and no need for derivatization offers significant advantage to this technique. Other advantages of HPLC over GC including the ability to analyze compounds with low volatility, poor thermal stability, and allowing analysis of conjugates of drugs and metabolites remain with the analytical advantage of MS with the technique.

Capillary electrophoresis has been used for the analysis of a wide variety of analytes including the amphetamines. Practical use of this technique has grown significantly over the last few years. Capillary electrophoresis uses either electrophoretic or electrokinetic separation, or both. This technique allows analysis of analytes from various matrices with relatively little sample preparation and often no requirement for derivatization. Even separation of underivatized enantiomers has been accomplished with capillary electrophoresis. Capillary zone electrophoresis and micellar electrokinetic capillary chromatography are the two most commonly used methods of capillary electrophoresis. Studies evaluating parameters such as pH, stirring, temperature, addition of salts, and selection of sorbents has lead to significant improvements. Another advantage of capillary electrophoresis is the low sample volume requirements (commonly less than 0.1 ml). Disadvantages of this technique include the difficulty of combining with MS and automation allowing routine analysis of multiple samples in a reasonable

time. Advances in nanospray LC interfaces and sample stacking techniques together with improved automation may bring capillary electrophoresis into the mainstream as an analytical tool.

### Introduction

The term amplification usually refers to a process whereby the power of a signal is increased without altering its basic information-carrying characteristics. The signal may be electronic, hydrodynamic, acoustic, or, in our case, chemical.

The Commission on Analytical Reactions and Reagents of the International Union of Pure and Applied Chemistry (IUPAC) defines the term amplification as follows: ‘An amplification reaction is one which replaces the conventional reaction used in a particular determination so that a more favourable measurement can be made. The sequence can be repeated to provide a further favourable increase in measurement’. This definition avoids the ambiguity of the terms multiplication and magnification, previously employed, and it has definitively introduced the term amplification in the analytical literature.

A number of changes are necessary to adapt this definition to the present state of analytical methods, not only in inorganic and organic analysis but also in biochemical analysis. However, two basic ideas must be retained: the fact that the use of amplification reactions is a way of increasing the sensitivity of the analytical measurements, and that these reactions can be carried out in an iterative form.

Historically, as has been indicated by Friedrich Mohr, the first amplification method was introduced by Bunsen and Dupré and independently by Golfier-Besseyre for the determination of iodide by oxidation to iodate. After elimination of the excess of oxidant, the reaction of iodate with iodide provided a sixfold enhancement of the original amount of iodide as iodine.

This method was also employed by Winkler in 1900 and Hunter in 1909, the latter using sodium hypochlorite as oxidant.

The application of these procedures for the determination of iodine in organic compounds on the microscale, carried out in 1929 by Leipert, promoted the popularization of amplification reactions in analytical laboratory practice.

In the literature published during the last 25 years, several examples of amplification reactions can be found that enhance the analytical sensitivity obtainable in the direct determination of cations and anions, and also in the elemental analysis and the selective determination of organic molecules.

This article reviews the principles of amplification reactions and their use for analytical purposes, with particular reference to the mechanisms involved in the methods discussed, in order to systematize present knowledge about these reactions. On the other hand, new aspects, concerning enzymatic amplification reactions and the polymerase chain reaction, have been included to establish the similarities and differences between these reactions and the classical amplification procedures.

### Principles and Classification

According to the definition of amplification, the increase in the number of moles of the compound to be measured by an amplification reaction must be different from that obtained normally by a conventional stoichiometric reaction. Thus, the simple weighting effect obtained in the gravimetric analysis of cations with complex organic molecules cannot be considered amplification reactions. In amplification reactions, the mass of the compound is increased by a selected series of reactions.

There are two basic forms of amplification: (1) direct amplification, where the compound to be determined is amplified directly and is subsequently measured; (2) indirect amplification, where the

compound is associated with some other, which is then amplified and measured.

Both direct and indirect amplification processes can be implemented by various mechanisms:

1. Change of oxidation state. The amplification is based on the change of valency or oxidation state of the compound to be measured (direct) or that associated with a preceding one (indirect).
2. Amplification by alternative precipitation. The precipitation of two salts of the same compound, with different stoichiometries, is employed as a basis for cyclic amplification of an anion or a cation.
3. Amplification with a complex of the ion to be amplified. This combines precipitation and valency-change processes.
4. Transportation. The compound to be amplified is employed for the transport of an equivalent amount of a reagent from one place to another. Amplification by the use of ion exchangers is a particular case of this general type of amplification process.
5. Alternate addition of equivalent amounts of two reagents. This involves a cyclic process in which a bare excess of reactant is alternately added to the specimens to be determined and the stoichiometric precipitates of the starting concentration collected after each cycle.

The two last cases are actually examples of iterative amplifications but *sensu stricto* do not suppose the use of any alternative reaction.

The parameter that defines the amplification procedures is the amplification factor,  $f$ , the quotient between the amplified amount of a compound that is measured,  $y$ , and the starting amount,  $x$ , to be amplified (eqn [1]):

$$f = y/x \quad [1]$$

Each amplification reaction provides a given factor  $f$  as a function of the reactions carried out. However, all the above-mentioned procedures can be applied several times before the measurement step, providing a cyclic amplification whenever the product of an amplification reaction can be transformed by whatever series of reactions into the original amplifiable compound.

Cyclic amplification complicates the experimental procedures but increases extraordinarily the amplified number of moles obtained.

Cyclic processes can be classified as arithmetic and geometric, depending on the relation between the amplified number of moles and the amplification factor obtained in each cycle. When at each single cycle the same amount of reagent is obtained, this can be termed arithmetic amplification. Thus, the following

relationship holds between the amplified number of moles,  $y$ , and the starting number,  $x$ , as a function of amplification factor  $f$  and the number of cycles,  $n$ :

$$y = fnx \quad [2]$$

Weisz has used the term multiplication to describe this kind of cyclic amplification, but the term arithmetic cyclic amplification is preferable to avoid misinterpretation.

In other cases, the amount of substance in circulation does not remain constant in each step but increases following a geometric progression and the amplified number of moles increases exponentially with the number of cycles as follows:

$$y = f^n x \quad [3]$$

Emich has suggested the term exponential method for these cases, but it might equally well be called cyclic geometric amplification.

In the following sections, several applications of each type of amplification mechanism are discussed.

## Applications

### Change of Oxidation State

The determination of iodide, after preceding oxidation to  $\text{IO}_3^-$  and reaction of the iodate formed with an excess of  $\text{I}^-$ , is an example of direct valency exchange process. **Scheme 1** summarizes the experimental procedure involved.

This method, very common in the analytical literature, gives an amplification factor of 6 and is the basis of a large number of amplification reactions. It can be applied using different oxidants, such as chlorine or bromine water, or sodium hypochlorite. A method has been proposed for the simultaneous determination of iodide and bromide ions, and also for the determination of iodine and bromine in organic compounds. The method is based on the oxidation of both ions to their halates and titration of the iodate and bromate after reaction with iodide for

**Scheme 1**

iodate at pH 3.8–4.1 and at a lower pH for the bromate–iodide reaction.

On the other hand, when  $I^-$  is oxidized by  $IO_4^-$ , a factor of 24 can be achieved as shown in Scheme 2.

Another example of direct valency exchange amplification is the method suggested by Emich in 1933 and developed by Schöniger in 1966 for the amplification of microgram amounts of  $CO_2$  by a cyclic geometric amplification procedure (Scheme 3).

The consecutive use of reductions with Pt/C and oxidations on CuO can also provide water amplification by the series of reactions shown in Scheme 4, which is one example of an indirect amplification procedure.

Reactions based on the equilibrium of the iodide/iodate system have been used extensively for indirect amplification, and a large number of mechanisms can be differentiated, such as metathesis of anions with  $IO_3^-$  or  $I^-$ , precipitation of cations with  $I^-$ , reduction with

$I^-$ , oxidation with  $I_2$ , oxidation with  $IO_4^-$ , oxidation of thiocyanate–metal complexes, bromination and reduction with  $I^-$ ,  $S_N2$  substitution and oxidation with  $Br_2$ , and complexation of cations with ethylenediaminetetraacetic acid (EDTA) in the presence of  $Pb(IO_3)_2$ .

The reaction of anions with  $AgIO_3$  is a typical example of ‘indirect amplification by metathesis’ and, as can be seen in reaction [I], it gives sixfold amplification:

As summarized in Table 1, anions other than  $Cl^-$  can be amplified in the same way.

Hassan and Thoria have developed an amplification procedure for the determination of organophosphorus compounds (triphenyl phosphine, tritolylphosphate, diethylbenzyl phosphates, tri-n-butylphosphine oxide, and triphenyl phosphate). The method is based on combustion of the organic compound in an oxygen-filled flask and the formation of the secondary form phosphate by adjustment of the pH value of the combustion product. Calcium iodate is then added and the  $IO_3^-$  released is treated with  $I^-$  to obtain an amplification factor of 12.

One example of indirect amplification by metathesis of anions with  $I^-$  is the determination of  $S^{2-}$  after reaction with  $AgI$  (reaction [II]):

$I^-$  is then amplified by oxidation to  $IO_3^-$  and in this case an amplification factor of 12 is obtained.

Precipitation of cations with iodide and further oxidation of the precipitates to obtain  $IO_3^-$  involves an indirect method of amplification by valency exchange.

$Ag^+$  can be amplified six times by the reaction [III]:

$IO_3^-$  is then amplified according to Scheme 1.

Scheme 2

Scheme 3

Scheme 4

**Table 1** Applications of indirect amplification by metathesis of anions

Anion	Compound added	Amplification factor, <i>f</i>
SCN <sup>-</sup>	AgIO <sub>3</sub>	6
CN <sup>-</sup>	AgIO <sub>3</sub>	6
SO <sub>4</sub> <sup>2-</sup>	Ba(IO <sub>3</sub> ) <sub>2</sub>	12
F <sup>-</sup>	Ca(IO <sub>3</sub> ) <sub>2</sub>	6
HPO <sub>4</sub> <sup>2-</sup>	Ca(IO <sub>3</sub> ) <sub>2</sub>	12
PO <sub>4</sub> <sup>3-</sup>	Ca(IO <sub>3</sub> ) <sub>2</sub>	18
AsO <sub>4</sub> <sup>3-</sup>	Ca(IO <sub>3</sub> ) <sub>2</sub>	12
EDTA	Pb(IO <sub>3</sub> ) <sub>2</sub>	12

Other cations, such as mercury, bismuth, lead, and thallium, can be precipitated with iodide and amplified in the same way as silver with an amplification factor of 6. In the case of thallium iodide, 4 mol of  $I_2$  are formed because the change in oxidation state from Tl(III) to Tl(I) produces an additional mole of  $I_2$ .

Reduction of oxidizing compounds with  $I^-$  provides an indirect way for their amplification via **Scheme 1**. A typical example is the polarographic determination of peroxodisulfate (reaction [IV]):

In this case,  $IO_3^-$  is reduced to iodine and iodide and then amplified by **Scheme 1**, providing an amplification factor of 6. Alternatively, the use of periodate provides a 24-fold amplification procedure (see **Scheme 2**).

When the iodate formed, at the end of the amplification process, is reduced at a dropping mercury electrode, a single wave with six times the magnitude of that found for iodide is obtained, and so a 36-fold amplification is achieved. The polarographic reduction of the iodate formed after oxidation of iodide with periodate involves a 144-fold enhancement of the sensitivity.

Other oxidizing compounds, such as quinone, chloramine T, and nitrite, can be amplified in a similar way with an amplification factor of 6, or 36 when a two-step cyclic reaction is carried out.

Reducing substances can be indirectly amplified after oxidation with  $I_2$ . An example of this type of reaction is amplification of thiosulfate as follows (reaction [V]):

The  $I^-$  formed is amplified six times by **Scheme 1**.

Thiosulfate can be oxidized to sulfate in the presence of hydroxide and the iodide obtained treated with bromine water after neutralization of the excess alkali with  $H_2SO_4$ , providing an amplification factor of 48.

At pH 12, iodide forms hypoiodite, which oxidizes  $S_2O_3^{2-}$  to  $SO_4^{2-}$  (reaction [VI]):

After acidification, the excess of  $OI^-$  is converted to  $I_2$ , which is then extracted. The oxidation of the remaining  $I^-$  with bromine water produces  $IO_3^-$ , which reacts with an excess of  $I^-$  to form 24 mol of iodine.

Thiocyanate is oxidized by  $I_2$  in a hydrogen carbonate medium (pH 8.2) to sulfate (reaction [VII]):

Acidification of the solution of pH 2.5 with  $H_2SO_4$  causes the reaction between iodine cyanide and iodide as shown in reaction [VIII]:

Thus, the overall reaction [IX]:

The oxidation of the remaining  $I^-$  with bromine after removal of iodine with chloroform results in the formation of  $IO_3^-$  from  $I^-$  and the oxidation of HCN to BrCN.

After destruction of the excess bromine with formic acid, the addition of potassium iodide provides 38 mol of iodine, 36 mol from the 6 mol of  $IO_3^-$  and 2 additional moles from the  $I_2$  formed in reaction [X]:

Other examples of indirect amplification after oxidation with  $I_2$  are summarized in **Table 2**. Especially interesting is the method developed by Amin and Al-Allaf for the amplification of the iodometric determination of organolead compounds, using **Scheme 1**, because in this case alkyllead and phenyllead compounds show different behavior. Phenyllead reaction products with  $I_2$  are extracted quantitatively into an organic phase, whereas in the determination of ethyllead compounds the reaction products

**Table 2** Examples of indirect amplification after oxidation with  $I_2$

Organolead compounds	3–12

containing iodine are extracted into an aqueous phase. Thus, both types of compound can be determined in a mixture. Amplification factors from 3 to 12 have been obtained in each case.

Reducing compounds react with periodate to give an equivalent amount of iodate that can be amplified, and so oxidation with  $\text{IO}_4^-$  at pH 7 provides another path for indirect amplification. A typical example is the 1:20 amplification of  $\text{Mn}^{2+}$  by reaction [XI], in which

Chromium(III) can be amplified in the same way with  $f=12$ ; antimony(III) with  $f=6$ ; and sulfur dioxide with  $f=6$ .

Other organic compounds, aldoses (such as glucose, mannose, or galactose), and glucose-1-phosphate have been amplified after oxidation with  $\text{IO}_4^-$ .

Besade and Gawargious have carried out the iodometric submicro determination of  $\alpha$ -aminoalcohols with amplification factors of 6, 12, and 18 for primary, secondary, and tertiary amino groups, respectively, owing to the stoichiometry of the oxidation reactions with  $\text{IO}_4^-$ .

Triphenylphosphine, triphenylarsine, and triphenylstibine can be amplified by oxidation with periodate in acidic or alkaline medium and iodometric titration of the iodate ion released. Two reaction routes (reactions [XII] and [XIII]) can be employed, where  $Z = \text{P}, \text{As}, \text{or Sb}$ :

In both cases an actual amplification factor of 3 is achieved.

All the above reactions can be carried out using molybdate at pH 3, as masking agent of the excess of periodate, as first proposed by Burnel in 1965.

One special case of indirect amplification via iodine oxidation is offered by the reaction with thiocyanate in sodium bicarbonate alkaline medium (reaction [XIV]):

One of the seven iodide ions formed reacts, at acid pH, with the iodine cyanide as shown in reaction [XV]:

After extraction of iodine, reaction with an excess of bromine provides 6 mol of  $\text{IO}_3^-$  per mole of  $\text{SCN}^-$ , which are amplified in the classical way. On the other hand, bromine oxidizes HCN providing BrCN, which reacts with 2 mol of  $\text{I}^-$  to form an additional mole of iodine, and so an amplification factor of 38 is obtained for  $\text{SCN}^-$ .

The amplification of  $\text{SCN}^-$  can be used as a basis for the amplification of metals by oxidation of thiocyanate metal complexes and several examples of this have been published, such as the amplification of Pb after formation of  $\text{Pb}(\text{SCN})_3[\text{N}(\text{C}_4\text{H}_9)_4]$ , in which  $1\text{Pb} \equiv 114\text{I}$ , or after forming  $\text{Pb}_3[\text{Cr}(\text{SCN})_6]_2$ , in which  $1\text{Pb} = 152\text{I}$ , and the amplification of bismuth via formation of  $\text{Bi}[\text{Cr}(\text{SCN})_6]$  or  $\text{Bi}(\text{SCN})_6[\text{N}(\text{C}_4\text{H}_9)_4]_3$ , in which cases an amplification factor of 228 is obtained.

Bromination of organic compounds and subsequent reaction with iodide provides an indirect amplification based on the extraction of the iodine liberated, reduction to iodide, and iodometric titration of the iodate formed by Scheme 1. By this method phenol is amplified 12 times and resorcinol and phloroglucinol 24 times. Other compounds, such as salicylic acid, acetylsalicylic acid, and *p*-hydroxybenzoic acid, have been also amplified.

Nucleophilic bimolecular substitution of alkoxyl and oxidation of the iodide liberated from the distilled alkyl iodide provides a sixfold indirect amplification procedure as seen in reaction [XVI], where  $\text{IO}_3^- \equiv 3\text{I}_2$ :

As previously described, the reaction of ethylenediaminetetraacetic acid (EDTA) with  $\text{Pb}(\text{IO}_3)_2$  provides an indirect amplification procedure based on the formation of 3 mol of  $\text{I}_2$  per mole of  $\text{IO}_3^-$ .

Complexation of cations with EDTA in the presence of  $\text{Pb}(\text{IO}_3)_2$  provides indirect amplification, which has been applied to the determination of Bi, Fe, In, Hg, Th, Cu, Ni, Pb, Zn, Cd, Co, and Al.

The general procedure consists of the addition to the sample of a known excess of EDTA and some lead iodate. The fraction of EDTA that remains unreacted with the cation liberates an equivalent amount of iodate, which is then amplified by reaction with iodide, after filtration.

In a similar way to that reported for the iodide-iodate system, the bromine-bromate can be used to provide amplification of several species.

Although the indirect determination of phosphorus, as molybdophosphoric acid, is not considered an example of an amplification reaction by several authors, because it is based on a favorable stoichiometry more than on the use of an alternative reaction, Belcher and Uden have proposed an actual amplification

procedure, based on the precipitation of molybdenum with oxine and titration with potassium bromate. In this case, each mole of oxine consumes 4 equivalents of standard bromate solution and, taking into account that  $\text{MoO}_2(\text{C}_9\text{H}_6\text{ON})_2$  is formed between molybdate and oxine, a final amplification factor of 96 for phosphorus can be obtained.

### Alternative Precipitation

The direct amplification of silver can be carried out by precipitation with chromate.  $\text{Ag}_2\text{CrO}_4$  is filtered and then treated with barium chloride for the precipitation of both  $\text{BaCrO}_4$  and  $\text{AgCl}$ . These precipitates are treated with  $\text{Ag}^+$  and thus 1 mol of  $\text{Ag}_2\text{CrO}_4$  and 2 mol of  $\text{AgCl}$  are formed.

The process can be repeated, and on each treatment with  $\text{BaCl}_2$  an amount of silver chloride equivalent to twice the original silver chromate is produced; after  $n$  cycles  $2(n+1)$  moles  $\text{AgCl}$  can be found.

This procedure can also be applied for the indirect determination of  $\text{CrO}_4^{2-}$ , by measuring the  $\text{AgCl}$  obtained.

One other indirect amplification, similar to those mentioned, is the amplification of phosphate by precipitation of silver phosphate and its conversion to silver chromate.

A particular case of the alternative precipitation method, which Weisz called cyclic amplification by fixation of both ions of an amplifiable compound, requires that the substance to be amplified be subjected to a series of stoichiometric reactions in order to enhance its mass.

**Scheme 5** for the amplification of hexacyanoferrate(II), via precipitation of the silver salt and formation of silver chloride and Prussian Blue by reaction with iron chloride, shows that it is a particular case of the alternative precipitation method in which the amplification takes place by a cyclic procedure.

This is an indirect procedure, but silver can also be amplified in a direct way by measuring the final  $\text{AgCl}$  formed.

**Scheme 5**

Weisz has applied this type of amplification reaction to the determination of phosphate, hexacyanoferrate(II), chromate, zinc, iron, and silver, and has obtained amplification factors up to 153 in a series of cyclic processes carried out in an automated form.

### Amplification with a Complex of the Ion to be Amplified

In this method the ion to be amplified is precipitated with a ligand containing the same ion, and then a cyclic procedure can be carried out. In general, this kind of amplification provides a geometric amplification factor.

Cobalt can be amplified by precipitation of hexaamminecobalt(III)–hexanitritocobaltate(III); the precipitate is then dissolved in  $\text{NaOH}$  and reduced to cobalt(II) with hydroxylamine. The doubled amount of cobalt produced in this step is converted again to hexanitritocobaltate(III) and precipitated with hexaammine cobaltate(III) following the cyclic procedure indicated in **Scheme 6**.

This process provides a twofold amplification in each cycle. The same system can provide a fourfold amplification if cobalt is converted to  $\text{Co}(\text{NH}_3)_6^{3+}$  and then precipitated as  $[\text{Co}(\text{NH}_3)_6][\text{Co}(\text{NH}_3)_2(\text{NO}_2)_4]_3$ .

Other examples of the same type are the amplification of  $\text{Ag}^+$  by reaction with  $(\text{Ag}(\text{CN})_2)^-$  to form

**Scheme 6**

2 mol of AgCN, and the reaction between Hg(II) and  $(\text{HgI}_4)^2$  to form 2 mol of  $\text{HgI}_2$ .

### Amplification by Transportation

Based on the principles of cyclic iteration, Weisz proposed the term transportation to define an amplification method in which an equivalent amount of a reagent is transported, by the compound to be amplified, from one place to another.

The transportation method involves an arithmetic increase of the amount of the substance to be measured, but it is not based on an alternative reaction and so cannot be considered an example of amplification *sensu stricto*, considering the definition of the term by the IUPAC.

The reaction between micromolar amounts of EDTA and solid mercury iodate is an example of the transportation process based on alternative precipitation. EDTA provides the solubilization of an equivalent amount of iodate and the formation of an Hg(II)-EDTA complex. The filtrate is treated with  $\text{Ag}_2\text{S}$  and the EDTA liberated is added to the original sample and brought back into the cycle.

With the aid of ion-exchange columns the amplification of cations and anions by transportation can be carried out using the following procedure. An aqueous solution containing a cation such as  $\text{Na}^+$ ,  $\text{Ca}^{2+}$ , or  $\text{Mg}^{2+}$  is applied to a cation-exchange column (in the acid form) and there it liberates an equivalent amount of protons. The solution obtained is introduced to another column (in the basic form) and liberates an equivalent amount of sodium ions, which are again passed through the acid form column, and so on. After  $n$  cycles all the protons on the cation exchangers are eluted with NaCl and titrated providing  $n \times m$  times the starting amount of the ion to be amplified,  $m$  being the charge of the ion considered (Scheme 7).

In a similar way, anions such as  $\text{Cl}^-$  and  $\text{Br}^-$  can be amplified using anion-exchange resins in the  $\text{OH}^-$  and  $\text{Cl}^-$  forms.

In all these cases an arithmetic cyclic amplification takes place and, experimentally, up to five cycles have been performed with good results.

Scheme 7

### Amplification by Alternate Addition of Equivalent Amounts of Two Reagents

Weisz has proposed a general methodology that permits cyclic amplification of the mass of a compound to be determined gravimetrically. This method, called alternate addition of equivalent amounts of reagents, is based on the addition, to the compound to be amplified (A), of a slight excess of another compound (B), which forms a stoichiometric product (AB). The reaction product is then collected and an amount of A equivalent to that initially employed of B is added; the product obtained is discarded and the procedure is reinitialized. After  $n$  cycles the mass of the product to be measured has been amplified  $n$  times.

Scheme 8 describes the experimental procedure. The process has been employed for the amplification of silver (using  $\text{Cl}^-$ ), lead (using  $\text{CrO}_4^{2-}$ ), nickel (using dimethylglyoxime), and copper (using benzoin oxime).

This procedure demonstrates that chemical amplification can be obtained without seeking an alternative process, but rather only including a 'touch of imagination' in our current chemical process. It has been included in the present article for that reason. However, neither alternate addition of equivalent amounts of two reagents nor the transportation method is an amplification reaction.

### Enzymatic Amplification Reactions

Catalytic reactions constitute a special type of reaction mechanism in which a chemical amplification takes place. With very low catalyst concentrations a significant amount of reaction product can be measured, enhancing the analytical sensitivity of the measurements. In general, these reactions are not amplification reactions. However, in some enzymatic reactions, a series of enzymes and other co-factors act on each other in a sequential fashion, providing a cascade reaction or, in a cyclic process, providing a rapid, amplified response of the small initial signal, and these processes can be considered examples of amplification reactions.

Metabolic pathways provide interesting examples of cyclic amplification processes and there have been described more than 140 enzymes and other proteins

Scheme 8

whose biological activity can produce a chemical amplification. In general, their activity is controlled by reversible covalent modification and two particular mechanisms can be found: substrate cycles and interconvertible enzyme cycles.

However, the sense of the term amplification in enzymology is not exactly the same as that previously considered for inorganic and organic reactions. In some cases, it is employed to indicate the enhancement of the total rate of a reaction by increase in the activity of one enzyme and decrease in the activity of another that acts on the same substrate, but in an opposite way. On the other hand, the synthesis of an active form of an enzyme from another can cause improvement in the effect of an external factor. The analytical chemist can exploit these situations in order to improve the sensitivity of determinations.

The processes mentioned can be applied in the analytical laboratory; for example, the determination of nicotinamide adenine dinucleotide phosphate (NADP) has been amplified by enzymatic reaction. The process consists of the addition to the sample of a mixture of  $\alpha$ -ketoglutarate, ammonium ion, and glucose-6-phosphate, which act as substrates, and controlled amounts of glutamate dehydrogenase and glucose-6-phosphate dehydrogenase enzymes. It initializes the cyclic reactions (Scheme 9), which provide increasing amounts of glutamate and 6-phosphogluconate. After the cycling sequence, the mixture is treated to destroy the enzymes and the 6-phosphogluconate is measured.

With large amounts of the two enzymes, more than 20 000 cycles per hour can be carried out and an overall amplification of the order of  $10^8$  can be achieved, enabling the assay of an amount as small as  $10^{-19}$  mol of NADP.

This example indicates the large number of amplification processes in biological systems that can be translated to laboratory scale and provide alternative

techniques to solve sensitivity problems in laboratory practice.

## Nucleic Acid Amplification Technologies

Detection and analysis of DNA and RNA present particular problems for the analytical biochemist because of the very low concentration of analyte. Often only one or two copies of a given sequence are present in the sample. Without either target or signal amplification, detection of such rare sequences is not feasible.

### Polymerase Chain Reaction

Nucleic acid amplification enables detection of nucleic acid sequences using laboratory methods analogous to processes that occur *in vivo*. The first such technology to be described was the polymerase chain reaction (PCR), which uses sequence-specific oligonucleotide primers and a thermostable DNA polymerase to carry out *in vitro* DNA replication. Repeated cycles of heat denaturation, primer annealing or hybridization, and primer extension by the polymerase facilitate synthesis of millions of copies of the original target sequence. DNA amplification by PCR can be coupled with reverse transcription of an RNA template to a complementary DNA (cDNA), thus enabling RNA detection by closely similar methods (reverse transcription PCR). Quantitative PCR methods provide information on gene expression levels. *In situ* PCR enables spatial localization of particular RNA transcripts in cells on a microscope slide. As a result of its preparative and analytical utility and the ease of assay configuration, PCR is almost universally used in basic research, clinical diagnosis, molecular genetics, veterinary science, human identification, microbial testing of food and environmental samples, archeochemistry, and other fields where there is a need for sensitive analysis of nucleic acids.

### Other Target Amplification Methods

In addition to PCR, there are many other technologies to amplify nucleic acids. For example, ligation-based amplification or ligase chain reaction uses sequence-directed oligonucleotide primers and thermostable DNA ligase to assay point mutations, deletions, or insertions in DNA. Strand-displacement amplification uses the inherent strand-displacement activity of DNA polymerases to conduct DNA amplification at a constant temperature. Transcription-based methods such as nucleic acid sequence-based amplification (NASBA) involve *in vitro* RNA transcription. NASBA and most other transcription-based

**Scheme 9**

methods have three major advantages over PCR: (1) RNA templates do not have to be converted to cDNA before amplification; (2) RNA transcription is isothermal and thus does not require thermal cycling instrumentation as does PCR; and (3) RNA products are less stable than the DNA products of PCR, making contamination of reagents with previously amplified products less likely.

### Signal Amplification in Nucleic Acid Analysis

Various signal amplification approaches have been developed to allow sequence-specific detection without a target amplification step. For example, branched DNA probes contain an analyte-specific sequence and a sequence tag that is used to bind probes for signal detection. The assay culminates in the attachment of an enzyme-labeled reporter probe to facilitate ultrasensitive chemiluminescent detection. Reporter probes tagged with a replicable sequence provide another means to amplify signal from an analyte. Thus far, signal amplification has been limited to relatively abundant targets, while PCR detection of single molecules is performed routinely.

### Introduction

During the last half-century, analytical chemistry has undergone a complete revolution. There are clear needs to establish compositions at forever-decreasing low levels of concentration and mass, in an ever-widening range of matrices for purposes as diverse as health and safety, materials science, the environment, and microchip technology. At the same time, laboratories have had to learn to cope with the analysis

of increasingly large numbers of samples. These pressures, together with improved understanding of the physicochemical principles of chemical separation, sensors, and spectroscopy, and the opportunities offered by progress in computing, electronics, and automation, have presented analysts with a huge choice of powerful, sensitive, and productive techniques for tackling their problems.

Some of these techniques permit direct examination of the sample and have little or no requirement for reagents. Most, however, are applied to solutions of samples, frequently after separation or preconcentration. As the role of classical analysis has declined from being dominant to relatively unimportant, there has been a reduction in demand for many reagents that were formerly widely used, such as the many organic chelating reagents for metals that were applied in gravimetric and colorimetric analysis, and used as spot-test reagents and metal indicators.

The techniques referred to above are still with us, of course, and it seems that no analytical approach ever completely disappears, but the range of classical methods that are still used has decreased very significantly, and suppliers of reagents have reacted by withdrawing many formerly popular reagent chemicals from their catalogs.

At the same time, new techniques have created demands for new reagents, as may be illustrated by mentioning derivatization reagents for gas and liquid chromatography, chemicals for electrophoresis, and nuclear magnetic resonance (NMR) shift reagents. More will be said about these developments in later sections of this article.

The present-day practitioner must have a very broad and detailed knowledge of available techniques, including areas of application, benefits such as speed, selectivity, and sensitivity, and limitations such as costs and sources of error, in order to make skilled judgements about methods and to take advantage of the range and diversity of the problem-solving capabilities of analytical chemistry.

It is also important that the chemist should make an educated selection of the other major tools of his profession, including chemical reagents. In many cases, advice is readily available from suppliers, especially with regard to the choice of materials for well-established analytical methods. However, the rate of change in analytical chemistry is fast, and when a new technique is employed there may not be chemicals readily at hand that are suited to the purpose, and they may not become available for many years until the demand is of sufficient commercial interest. In the meantime, the analyst is faced with the prospect of purifying materials. This is the subject of the second article in this entry on analytical reagents.

## The Concept of Purity Applied to Reagents

A pure compound is one that contains no molecules or ions other than those indicated in its chemical formula. In reality no such compound exists, of course, and so it is common practice in the chemical, pharmaceutical, and related industries to express the closeness with which substances approach the ideal by means of specifications controlling the impurities they contain to maximum permissible concentrations.

Other properties of the substance giving an indication of its purity level will be included, such as (depending on its nature) maximum allowable quantities of insoluble matter, nonvolatile matter or residue on ignition, the pH of solution, density, melting point or boiling range, refractive index, and specific rotation.

Another indication of degree of purity that is often used for an organic liquid is to establish that only one peak is produced under examination by gas or liquid chromatography using one or more sets of conditions.

It is possible for specifications expressing maximum limits of impurities to give a misleading view of purity if it is assumed that the supplier is aware of all the possible impurities that could be present in a given chemical and has taken steps to control them.

It is not advisable to assume that all significant impurities have been controlled, even when the specification is supported by an emission spectroscopic examination certificate stating that other impurities have not been detected. For example, a metal oxide might contain a significant amount of the carbonate, and a pure metal could contain a significant content of occluded oxygen. In general, a supplier will usually not be aware of the presence of an impurity that has never been specifically sought. Commercial considerations might also result in the omission from a specification of an impurity whose limiting concentration would detract from the high standard implied by the other requirements of the specification.

The analytical chemist's own knowledge of chemistry taken in conjunction with the published specification does, however, give a good guide to the purity of materials. First there are common associations, caused by similarities in chemical behavior, that are to be expected and indeed do occur in chemicals. In chlorides, for example, bromides would be expected to be present, and magnesium would be expected as an impurity in calcium salts. Low concentrations of bromide in a chloride and of magnesium in a calcium compound are good indicators of a high degree of purification.

All other expected relationships of elements or ions may be used in assessing the extent of purification of inorganic substances. Common associations include sodium and potassium; calcium, strontium, and barium; phosphorus and arsenic; arsenic and antimony; and iron, cobalt, and nickel. There are a number of less well known but useful associations that are often described in textbooks of geochemistry, including silver with lead and its compounds; arsenic with copper and its compounds; and manganese in magnesium compounds.

The degree of purity of an organic compound is less easy to judge from its specification, but a few very simple relationships can, with experience, be quite helpful. For example, control of isomers in substituted aromatic compounds, of homologs, of decomposition products, of products of simple oxidation such as corresponding acids in aldehydes, or of reduction such as corresponding alcohols in ketones, and of by-products from known synthetic routes.

Finally, it is important to mention the widely distributed and abundant elements sodium, potassium, calcium, magnesium, aluminum, silicon, and iron. These are present to some extent in the vast majority of chemical products and, although not an infallible guide, their concentrations indicate the degree of purification of a chemical and the care with which it has been handled, stored, and packaged.

## Classification of General Reagents

The fitness for purpose of a reagent may be impossible to judge unless it has a small number of applications. Chemicals such as nitric acid or ammonia solution have such a vast range of uses that it is unusual to find them specially prepared for any particular application. Suppliers will usually address this situation by offering a range of, say, three or four quality standards of the reagents, with specifications representing different degrees of purification, thus leaving analysts to select the brands most suitable for their work.

Thus, for one of the substances mentioned above that is available in, say, four grades, as a general rule, the cheapest grade will have the fewest 'maximum levels of impurities', controlled at mg per kg or even tens of mg per kg. The most expensive will have a long list of impurities controlled at sub- $\mu$ g per kg, possibly ng per kg concentrations.

It is important for the analyst to exercise good judgement in the selection of his reagents and this requires an understanding of the usefulness and possible limitations of chemical specifications. The use of very high purity reagents may add unnecessary

costs to an analysis, yet the failure to use an appropriate high purity chemical is often a false economy that leads to a greater increase in indirect costs than is saved by reagent costs being lower.

It is encouraging that, in recent years, many high purity liquids, ammonia solution, acetic acid, and the mineral acids, hydrogen peroxide solution, and a range of organic solvents, have become available mainly because of the responses of prime manufacturers to the stringent requirements of the microelectronics companies for high-purity processing chemicals for use in microchip production. As a consequence, not only have improved materials become available, but the use of ion chromatography, inductively coupled plasma (ICP) emission spectroscopy, and ICP mass spectrometry has enabled impurity profiles of these chemicals to be established for a wide range of substances, often for as many as 50 impurities, and most of them at  $\mu$ g per kg level or below.

This advance has had a knock-on effect for the long-established analytical reagents grade, in which significant improvements have been made to the materials and their specifications. Limits for most impurities in analytical grade acids, solvents, ammonia solutions, and hydrogen peroxide solutions are now quoted at  $\mu$ g per kg levels.

The quality control analyses of these chemicals are performed using almost the whole range of trace analysis techniques available. Among the most important are atomic absorption spectrophotometry in all its forms, ICP emission spectrometry, and ICP mass spectroscopy, ion chromatography, gas and liquid chromatography, ultraviolet and visible absorption spectrophotometry, voltammetry, and spectrofluorimetry.

These reagents, and many of those mentioned later, are also often assayed. The determination of the assay of a substance may be useful for many reasons: it may serve as a confirmation of identity via gross composition, to ensure that for a hydrated compound the correct hydrate has been manufactured, to provide concentration values for reagents that are supplied as solutions, such as ammonia solutions and mineral acids, and to assay materials that always contain quantities of water but not as hydrates, of which perhaps the commonest is sodium hydroxide.

Specifications are guarantees of minimum standards of purity and are not to be regarded as actual analyses or typical analyses. This point is frequently misunderstood and has caused some suppliers to quote typical or actual batch analyses. Neither of these conventions has any practical value to the user unless also backed by published specifications which ensure that the ranges of typical or actual batch data

do not include concentrations of impurities that would be unacceptable for the intended use.

It is also necessary for the user to take into account that fine chemicals for laboratory use are usually produced by batch processes rather than by continuous methods of manufacture. Therefore, because specifications set minimum standards of purity, the analysis of one or two batches of a given reagent from a supplier will not give reliable general information concerning the impurity profile of that product.

The convention of operating to specifications also introduces the possibility that a reagent supplied as a lower grade will meet the specification of a higher grade of the product. This occurs because of batch-to-batch variation and it would be unwise to draw any other conclusion. As a general rule, analysts should select as reagents for regular use only those materials whose specifications (either published or agreed with the supplier) meet the requirements.

### High-Purity Reagents

Reagents of somewhat higher purity than conventional analytical reagent grade are now increasingly required for a wide range of analyses in fields as diverse as the environmental, materials, and life sciences.

These were first required in the early 1950s when the UK manufacturers were asked by the Society of Public Analysts to provide high-purity acids and ammonia solutions for use in regulatory analyses of lead in foodstuffs. These 'low in lead' reagents were soon prepared with guarantees that they contained less than an agreed limit of 0.005 ppm (i.e., less than 5 µg per kg) of lead as determined by a specific colorimetric method based on dithizone. This was a significant achievement for the time and, as expected, as analytical sensitivities improved, the suppliers were able to confirm that the purification processes made significant overall improvements to the products. Low-in-lead reagents were manufactured in small batches but the lessons learned were transferable to a much larger scale when demand came within the next decade for high-purity processing chemicals for semiconductor manufacture.

Reagents of high overall purity include the acids, ammonia solution, hydrogen peroxide solution, and organic solvents previously discussed. Several high-purity solid substances having wide-ranging applications are also available to standards rather higher than those of the corresponding analytical grade materials. These include sodium hydroxide; a number of pH buffer components; ashing aids used when the resulting ash will be tested for trace elements; biochemical reagents such as ammonium sulfate,

sucrose, and urea; and matrix modifiers employed in graphite furnace atomic absorption spectrometry. The testing of these items usually involves multielement techniques such as ICP spectrometry and ion chromatography plus electrothermal atomic absorption spectrometry for selected metallic impurities, spectrofluorimetry, and gas chromatography or liquid chromatography as appropriate.

Ultrahigh-purity acetic acid, ammonia solutions, and mineral acids prepared by double subboiling distillation, having ng per kg impurity levels, are available commercially for use in the most demanding trace analyses.

### Standard Reference Materials

The International Standards Organization (ISO) has defined a reference material as a material or substance one or more properties of which are sufficiently well established to be used for the calibration of a method, or for assigning values to materials. The ISO definition of a certified reference material is a reference material one or more of whose property values are certified by a technical procedure, accompanied by or traceable to a certificate or other documentation that is issued by a certifying body.

Certified reference materials are used to provide reference values to facilitate the development and validation of analytical methods, and for the calibration, verification, and quality control of analytical measurement systems.

A standard reference material may therefore be either a highly pure reference compound or a well-characterized substance or a calibration standard.

Primary, secondary, and working chemical standards are high-purity chemicals. They have been defined by the Analytical Chemistry Division of the International Union of Pure and Applied Chemistry (IUPAC) as follows:

- A primary standard is commercially available and has a purity of 99.98–100.02%.
- A working standard is commercially available and has a purity of 99.95–100.05%.
- A secondary standard is a substance that may be of lower purity and which can be standardized against a primary standard.

From the earlier discussion on purity, it will be appreciated that an assay alone will not be sufficient to establish a primary standard unless it is certified for use in similar assays. It will generally be necessary to select material that can be established as highly pure by examination for all the impurities that may be

present. The tolerance values placed by IUPAC on the purity for a primary standard, for example, may then be interpreted as meaning that the sum of the impurities is not greater than 0.02% and that on assaying by a suitable high-precision method the calculated result falls between 99.98% and 100.02%.

High-purity materials are available as pure solids for chemical uses such as metals used as reference substances for metallurgical analysis, and compounds used as primary standards for many types of titrimetry, and as standards for elemental microanalysis. Other available high-purity substances intended for diverse physical properties include ion activity standards for the calibration of pH and ion-selective electrodes; standards for various thermodynamic uses including melting point determinations, differential scanning calorimetry and bomb calorimetry; and standards for the calibration of spectrophotometers.

The majority of chemical reference materials (CRMs) are widely analyzed materials having one or more chemical or physical properties sufficiently well established to be used as reference values for calibration or performance assessment. Items as diverse as gas chromatography-mass spectrometry system performance standards, human or bovine serum, fly-ash, soils, estuarine sediments, rice flour, and stainless steels are included in the vast range of CRMs available.

Standard solutions and gas mixtures are also available for many single- and multisubstance techniques; for example, drug assay standards, standard solutions of metals in single- or multielement form, and carbon monoxide and nitrogen dioxide in air.

Finally, there are many authentic specimens and fairly high-purity organic materials that are used to confirm chromatographic retention times and infrared, NMR, and mass spectra.

There are three methods of establishing a certified reference value. The first is to use an established reference method that is based on fundamental principles and that has high precision and negligible bias so that the uncertainty limits of the certified value are small. This work may be performed by one laboratory or a small number of laboratories. Another method often used for organic substances and carried out by one laboratory is to use two or more methods that have been shown to be reliable and that are based on different principles. An important criterion for acceptance of data when using this approach is that the values obtained by each of the methods employed must fall within the permissible uncertainty interval of the end-use of the substance. The third method is to use the statistically established 'consensus' value obtained from a cooperative study in

which many laboratories conduct analyses of the substance, preferably using a number of different analytical methods, including any established reference method.

## Organic Reagents for Inorganic Analysis

A generation ago, when much of analysis still consisted of classical and colorimetric methods, several hundred organic reagents were available to the analyst. Although the use of these methods has declined very considerably, they are still used and several of the better known organic reagents remain listed in the suppliers' catalogs.

Organic reagents found applications as precipitants for gravimetric analysis, extractants for separating small quantities of metals, colorimetric reagents, titrants (principally ethylenediaminetetraacetic acid (EDTA)) and metal indicators for complexometry, and masking agents to prevent undesirable reactions from occurring during analysis.

Organic reagents are weak acids or bases, and in their conjugate base forms they provide ligands that combine with metal ions to form coordination complexes. The most stable complexes are generally formed when the ligands are chelating, that is they have two or more combining functional groups so that each ligand group occupies two or more coordination positions.

Some organic reagents are selective and react with very few metals, but the majority are far from selective. However, highly selective conditions may often be derived using pH control and masking and sometimes careful oxidation or reduction of potential interferents.

Some of the most successful and widely used chelating reagents include dimethylglyoxime for the gravimetric determination of nickel; 1,10-phenanthroline and its derivatives for the colorimetric determination of iron and copper; dithizone for the separation and colorimetric determination of a number of metals but particularly lead, silver, zinc, cadmium, and mercury; the dithiocarbamates such as diethylammonium diethyldithiocarbamate and ammonium pyrrolidinedithiocarbamate, used for colorimetry but more widely applied now as selective extractants; and the most successful titrant, EDTA.

Two flow techniques in particular, the use of liquid chromatography or ion-exchange chromatography to separate metal ions followed by postcolumn derivatization of the metals in the effluent, and the determination of metals by flow-injection analysis, have created further applications for suitable organic

chemical reagents. Colorimetric methods using organic reagents are also employed in automatic high-productivity techniques, such as in discrete analyzers used in clinical biochemistry and water-industry laboratories. Colorimetric reagents will also be considered in the next section of this article.

Other types of organic reagent include those used to form colored ion-association systems, precipitants forming insoluble normal salts, and the insoluble salts of chloroanilic acid.

Some dyestuffs form ion-association systems with large inorganic anions. Brilliant green co-extracts stoichiometrically with hexachloroantimonate ion, providing a method for the determination of antimony.

The normal salts of several carboxylic acids such as oxalic, benzoic, and mandelic acids are insoluble and useful gravimetric methods were based on this property. It is also worth mentioning that sodium tetraphenylmetaborate is soluble, whereas its potassium salt is insoluble, and that selective gravimetric and titrimetric methods are thus possible.

The insoluble salts of chloroanilic acid may be exemplified by barium chloroanilate, which is still used for the automated monitoring of sulfur dioxide emissions, after conversion to sulfate with hydrogen peroxide. Solid barium chloroanilate reacts with solutions containing sulfate to form insoluble barium sulfate, thus releasing an equivalent concentration of chloroanilic acid, which is measured by ultraviolet spectrophotometry.

The standards of organic reagents vary widely. Several of the better-known reagents are available as analytical reagent grade products, but the majority has lower and variable purity, especially those that are produced primarily as commercial dyestuffs. They are usually tested only to ensure that they give the required color reactions or precipitates and, as they are normally used to a large extent to the determination of this type of examination is insensitive to batch-to-batch variation.

## Chromogenic Reagents, Including Indicators

Chromogenic reagents include the various kinds of chemicals used as pH indicators (for both aqueous and nonaqueous systems), redox indicators, metal indicators, giving changes usually in color but also in fluorescence or luminescence, and reagents used for visual and/or absorptiometric colorimetry.

The indicator properties result from the different colors of the conjugate acid–base forms of the materials used as pH indicators, or of the oxidized and reduced forms of redox indicators, and the

metal-complexed and uncomplexed forms of the metal indicators. Fluorescent or chemiluminescent indicators have advantages for use in colored or turbid solutions, and for remote sensing.

The most common acid–base indicators are either azo dyes: for example, methyl orange and methyl red; nitrophenols; phthaleins such as phenolphthalein or thymolphthalein; or sulfonephthaleins like bromophenol blue or bromocresol green. Acid–base indicators are available that cover visual transitions usually expressed in intervals of 2 pH units ranging from pH 0.0 to 2.0 in small increments up to pH 12.0–14.0.

Redox indicators include indophenols: for example, 2,6-dichlorophenolindophenol; azine dyes such as the well-known thiazine dye methylene blue; indigo carmine and other indigo derivatives; derivatives of diphenylamine including diphenylamine-4-sulfonic acid and variamine blue; and the 1,10-phenanthroline–ferrous complex.

Metal indicators include a number of well-known organic reagents: for example arsenazo III, catechol violet, dithizone, 1-(2'-pyridylazo)-2-naphthol, and 4-(2'-pyridylazo)resorcinol. Also included among metal indicators are several commercial dyes such as chrome azurol S, eriochrome black T, eriochrome blue-black B, and pyrogallol red. Finally, there are the 'designer' metal indicators containing Mannich reaction-substituted iminodiacetic acid groups, exemplified by alizarin complexone, methylthymol blue, and xylenol orange.

As a general rule, these indicators are, with a few exceptions, somewhat impure and full chemical analysis shows large batch-to-batch variations. They are, however, normally tested for their suitability as indicators under standard conditions of use, and their measured visual or instrumental transition intervals must usually comply with standards set to ensure parity of performance between batches.

## Other Developments in Analytical Reagents

### Special-Purpose Reagents

Since the 1960s the trend in reagent supply has been increasingly toward the introduction of chemicals intended for specific applications. Reagents were first provided for techniques such as ultraviolet spectroscopy and later for liquid chromatography, electrophoresis and so on, and for special areas of application such as histology, hematology, and electron microscopy, and also for specific purposes like the NMR shift reagents.

Other special-purpose reagents include many of the convenience reagents discussed in the next section and, of course, a huge range of materials for chromatography including materials for supports, stationary phases, silylating reagents, and derivatization reagents.

In general, the quality control of these items consists of ensuring that they are suitable for the intended purpose. Some, such as the ultraviolet and liquid chromatography solvents are of intrinsically high standard, but others, particularly stains for histology, may be chemically far from pure. The analyst must therefore be particularly cautious if using such a reagent for any purpose other than that for which it has been listed by the supplier.

### Convenience Preparations

The most familiar convenience reagents are acid–base and pH indicator papers. Several other types of indicator papers exist for redox and more specific test purposes; for example, the estimation of glucose in blood and urine. The principle has been extended using a range of colorimetric reactions into the use of test kits for rapid and semiquantitative analyses, particularly of waters and soils. Reagents impregnated onto inert support materials in tubes through which measured amounts of air are drawn are used in large quantities to monitor workplace environments. These tubes are available for many different substances. Color reactions in the tubes give estimates of the concentrations of the tested species that are present in the air.

Convenience reagents also include ready-to-use buffers, bench reagents, and standard solutions and indicators for titrimetry. Buffers and standard volumetric solutions are also available in concentrated form so that a simple volumetric dilution of the contents of a container will produce the required reagent concentration.

Standard solutions of inorganic species, both non-metals and metals, are particularly widely used in laboratories. Multielement metal standards, for use in ICP emission spectroscopy and other multielement techniques, must be backed with a guarantee that high-purity components are used in their formulation; otherwise, trace impurities in the individual ingredients may contribute significantly toward total quantities of the very elements it is required to measure. Undesirable ‘blanks’ of this kind are easily overlooked and can seriously degrade analytical performance.

It is now common for manufacturers to offer ready-to-use reagents, often as complicated mixtures, for use in automated analytical procedures such as in clinical biochemistry and for online process control.

Methods of quality control (QC) of convenience reagents vary according to type. Simple solutions are controlled by analysis and for standard solutions an accuracy of 0.1% is required wherever attainable. Multielement metal standards are prepared from high-purity starting materials that have been well analyzed, and are tested by a multielement method to ensure that no extraneous contamination has occurred. Prepared reagent mixtures for specific applications and test kits are subject to both QC analysis of the individual components and then, after preparation, have to meet performance criteria.

### Introduction

Methods for the purification of chemicals belong to the realm of separation science. Every process for the separation of one species from others has been employed for purifying substances. The traditional techniques of distillation, precipitation, recrystallization, and, for many metals, refining and electrolysis, are the basic processes of purification and are, for most industrial and technical purposes, quite sufficient.

Most chemicals for analytical use are purified adequately by the application of traditional methods to selected starting materials, particularly for the regular analytical-reagent grades in which impurities are controlled at mg per kg levels. The success of these methods depends on the nature of the substances concerned and the degree of purity of the starting materials in respect both of overall purity and of specific impurities that may be difficult to remove.

The important relationship that generally exists between the careful study and selection of raw materials and the purity of the finished products cannot be too strongly emphasized, and may be assumed to apply to the methods presented throughout this article.

Another important general consideration for the improvement of purity is the choice of materials for the construction of the apparatus in which purification operations are to be performed. The most appropriate materials to withstand chemical attack may nevertheless introduce undesirable impurities into the product. For this reason it is frequently necessary to run process trials in the equipment until available impurities have been leached from the apparatus.

For the highest grades of purity and for certain chemicals, the well-known techniques of distillation and recrystallization cannot be used, except as the first stages of purification. This is particularly true either when exceptional purity is needed or when an undesirable impurity is not separated by the physical process applied. In such cases two or more techniques may be successively applied to achieve purification. Alternatively, it may be necessary to use

different physical processes. The more common of these include sublimation, chromatography, and zone refining.

In many liquids, such as the mineral acids, impurities are known to be present in vast numbers of minute particles and significant purification is achieved by ultrafiltration under clean-room conditions.

The major impurity in a solid chemical is often water or the solvent from which it was crystallized, so that drying, or solvent removal, is another purification process.

Finally, there are numerous chemical methods for the removal of impurities. Such methods are aimed at reducing the concentrations of particular impurities and so it is not possible to describe them comprehensively. Instead, several examples are outlined to indicate the range of approaches that have been used successfully.

The variety of techniques available for the purification of small amounts of substance is particularly wide, and those that are used for very narrow ranges of chemicals or for submilligram quantities are not considered here.

### Distillation and Sublimation

#### Distillation

Distillation is one of the two most widely used techniques for the purification of liquids and low-melting-point solids. Simple distillation will only effect separation from solid impurities, of course, so that fractional distillation is more common, particularly for the purification of organic compounds, and with modern apparatus equipped with computer control it is possible to achieve very high levels of purity. Fractional distillation is applicable over a very wide range of quantities of substance from subgram amounts to the tonnages manufactured by the heavy organic chemicals industry.

Organic liquids with high boiling points or those that are liable to undergo partial decomposition when distilled at atmospheric pressure should be distilled or fractionally distilled at reduced pressure, the process being commonly called vacuum distillation. Some practical precautions that must be taken in vacuum distillation are dealt with in the first reference in Further Reading. It is important also to consider safety aspects that apply to particular chemicals, for example, that ethers may contain explosive, thermally labile peroxides, and should be tested

before use and chemically treated if necessary. Another important safety precaution to consider is that stills accommodating even a few liters of organic liquid may well need earthing and blanketing with inert gas to ensure safe operation.

Constant-boiling mixtures, known as azeotropes, are formed between several mixtures of two or more compounds. The commoner form of azeotrope has a constant boiling point lower than that of either component, and familiar examples include ethanol with water, benzene with cyclohexane, and methanol with methyl acetate. The less common azeotropes have boiling points higher than those of the individual components, and these include the well-known mineral acids, and mixtures of acetic acid with pyridine, and of acetone with chloroform. Methods for the separation of the components of an azeotropic mixture include chemical treatment, such as removing water with a molecular sieve or by 'salting out' the organic phase from an azeotrope with water; fractional crystallization of the mixture; and distillation with a third substance that forms a ternary azeotropic mixture. For example, benzene added to the ethanol-water azeotrope produces a lower-boiling-point azeotrope that can be distilled off to remove the water.

The technique of steam distillation is sometimes used in purification because it is fairly selective in that relatively few water-insoluble substances are steam-volatile, and because it facilitates the distillation of some compounds at temperatures well below their normal boiling points. The codistilled water is usually easily removed. Examples of its use include the distillation of nitrobenzene and naphthalene.

Acids and ammonia solutions intended for use in trace analysis present particular problems. They are widely needed, often in significant quantities, for a wide range of metal determinations. Their chemical reactivity presents the problem that during purification the apparatus employed must be carefully selected and conditioned to minimize its contamination of the product, and after it has been purified the containers for its storage present similar difficulties.

Many years ago, in response to the requirement for specially purified acids for use in the determination of lead in foodstuffs, suppliers provided 'low-in-lead' reagents that had been redistilled two or three times in well-conditioned glass or quartz apparatus that had been specially selected as being essentially lead-free. Later demands for larger quantities and a wide range of controlled impurities could be met by scaling up the process somewhat, but production by this means is expensive and does not yield product that meets the needs of current trace analysis capabilities: it delivers product that has roughly  $\mu\text{g kg}^{-1}$

impurity levels but not lower, because of carryover during distillation.

Laboratory-scale preparations of ammonia and volatile acid solutions intended for use in trace metal analysis have been successfully performed by isothermal distillation, usually at room temperatures. In this technique, two beakers, one containing the chemical being purified and the other holding pure water, are placed together in a sealed closed container for a few days. The volatile component becomes uniformly shared between the contents of the two vessels and nonvolatile impurities remain in the original beaker.

The most successful method for purifying volatile acids, ammonia solutions, and solvents, and which is operated on a small commercial scale, is that of sub-boiling distillation. The apparatus is constructed from quartz or, for hydrofluoric acid, of polytetrafluoroethylene (PTFE), and infrared radiators vaporize the surface of the liquid without bringing it to the boil. The vapor is condensed on a tapered 'cold-finger condenser' and the liquid is collected in a suitable container, itself constructed from quartz or PTFE. Apparatus is available that will deliver 20 or more liters per still per day.

Finally, mention must be made of so-called 'molecular distillation', which has been used to purify small amounts of compounds of low volatility, often for use as reference materials. At very high vacuum, the mean free path of a molecule becomes quite large, for example, several centimeters. Molecular distillation makes use of this fact. The liquid of low vapor pressure is evaporated under high vacuum with only a short straight-line distance between its surface and that of the condensing surface. This form of distillation uses much lower temperatures than ordinary vacuum distillation and significantly reduces thermal degradation of the product. The distance between the surfaces of the liquid and the condenser may be adjusted, for a given temperature of operation, to be within the mean free path of molecules of given relative molecular mass.

### Sublimation

In sublimation, a solid substance is volatilized by heating and the vapor is condensed back to the solid at a cooled surface. The distance between the surface of the vaporized solid and the collecting surface is short compared with distances used in distillation. Sublimation may be conducted at atmospheric pressure but reduced pressure is often employed to enhance sublimation and to speed up the process. An atmosphere of inert gas at low pressure is advisable for sensitive compounds.

Purification through sublimation is applicable to a number of organic and inorganic substances and is useful for the purification of many simple inorganic compounds used as working standards in analysis, including ammonium halides, arsenic(III) oxide, phosphorus(V) oxide, and iodine.

## Recrystallization

Recrystallization is the second of the two most widely used methods of purification. The normal procedure is to dissolve the substance to be purified in a suitable solvent, at an evaluated temperature, to form an almost saturated solution. It is then allowed to cool so that the dissolved substance crystallizes out. The crystalline product is then separated by filtration or centrifugation, leaving impurities behind in the solution or 'mother liquor', and is then washed free of mother liquor with successive small volumes of the cold solvent, and dried.

It is good practice to remove insoluble impurities from the original hot solution by filtration, so that they will not be included in the product, and this requires the use of a filter in which the high temperature can be maintained.

Organic compounds in particular may contain colored impurities and it is frequently possible to remove these by thoroughly mixing the original hot solution with activated charcoal before filtration and crystallization.

When chemical treatments are employed to remove selected impurities, they are usually also applied to the first stage of recrystallization. Chemical treatments are the subject of a later section of this article.

Second and subsequent recrystallization will usually improve purity, and for greater effectiveness two or more recrystallizations from different solvents should be used if possible.

Two considerations are worth noting. The first is that rapid crystallization is often recommended because slow crystallization gives larger crystals, which, although they look more perfect to the naked eye, quite often contain occlusions of mother liquor. However, trace chemical impurities tend to concentrate at crystal surfaces and so a high surface area is not compatible with best chemical purity. Preliminary recrystallization with slow cooling to produce well-formed crystals followed by a second recrystallization with rapid cooling has often been employed to overcome both problems.

Some substances have solubilities in certain solvents that do not vary significantly with temperature: a common example is sodium chloride in water. But because the equilibrium between a solid and

its saturated solution is dynamic, prolonged digestion of such a substance with the solvent has the effect of recrystallizing it.

Recrystallization does not always achieve the desired degree of purification. The author has experience of a few compounds that attained higher concentrations of certain impurities on successive recrystallizations. This is to be expected if an impurity has a crystalline form isomorphous with that of the bulk material or can in some way enter the host lattice, and this is often not possible to predict.

## Zone Recrystallization

Zone recrystallization incorporates practices from both recrystallization and column chromatography but is a purification technique in its own right. It is simple to operate, economical with both the substance to be purified and the solvents used, and is almost invariably conducted at room temperature, although in principle it can be operated at any temperature. It is very suitable for thermally labile substances and works satisfactorily for compounds of wide-ranging solubilities.

The chemical to be purified is evenly packed in comminuted form into a vertical column. A small volume of solvent liquid is introduced at the top of the column and allowed to percolate through under gravity. The solvent addition is controlled in quantity and rate so that after traveling a short distance along the column it has filled the interstices and has become a saturated solution of the bulk substance. Further small volumes of the solvent are added so that a number of solvent zones are present before the leading zone emerges from the column. The impurities are removed in the liquid effluent. Another solvent in which the host material is insoluble may be used to remove the original solvent.

## Chromatography

A variety of chromatographic methods are used successfully for the purification of small quantities of organic chemicals and biochemicals, based on both gas chromatography (GC) and liquid chromatography (LC).

Gas-liquid chromatography may be used, in principle, to separate the components of any volatile liquid in a column similar to, but somewhat larger than, an analytical column operated at a temperature a little greater than the boiling point of the substance being purified. It is normal practice to use partition (i.e., gas-liquid) chromatography with a packed column containing an inert support material coated with a suitable high-boiling-point liquid, of which a

number are available with different polarities. The separations are monitored using a nondestructive detector, such as a thermal conductivity detector, and the resulting chromatogram is displayed. As the components emerge from the column they are captured by condensation in high-efficiency strongly cooled traps.

Liquid chromatography is rather more widely applicable than gas-liquid chromatography and in some forms has the capability to handle larger amounts of substance. All the main forms of LC are used, namely adsorption, partition, ion exchange, and gel filtration, and some newer forms of chromatography including metal-chelate adsorption, hydrophobic adsorption, and, particularly for biochemicals, affinity chromatography.

The variety of types of adsorbents, solvents, stationary phases, ion exchangers and eluents, gels and special phases, and the numerous applications of chromatographic methods, have given rise to a vast literature on the subject, the review of which is beyond the scope of this article. Instead, some of the most widely used methods and a few of the more interesting applications are presented, and readers are advised to consult the chromatographic literature for more information.

Column chromatography has been practiced on quite significant amounts of material, and adsorption chromatography has been used on a commercial scale for the purification of an extremely wide range of organic compounds. Among the analytical reagents purified by this technique are solvents for ultraviolet spectrophotometry and liquid chromatography (LC), in processes that may also involve chemical treatment and distillation.

In principle, LC is similar to GC, but is more versatile because, whereas in GC only the polarity of the stationary phase can be varied to bring about or improve separation, in LC the polarities of both the stationary phase and the solvent can be varied widely, and also the elution can be performed with solvent programming by means of which the polarity of the eluent can be varied throughout the process as a further aid to separation.

LC uses high pressures to elute small samples through high-efficiency columns fairly quickly, and this combination of pressure and column efficiency results in much better separations than are possible with atmospheric-pressure chromatography systems. The technique can be used only for the purification of relatively small amounts of substance.

LC using chiral stationary phases has been used for the separation and purification of enantiomers and is attracting great interest, particularly because of the biological significance of chirality.

The technique of flash chromatography, in which a larger amount of substance is purified on a fairly high-efficiency column at a few atmospheres pressure, has proved quite useful and is employed, by the pharmaceutical industry for example, for the purification of small amounts of reference materials.

## Zone Refining

Impurities generally lower the melting points of solids or the freezing points of liquids. When an impure liquid is gradually cooled, the first crystals to form are usually purer than the remaining liquid. This principle is the basis of purification by the techniques of fractional solidification, recrystallization from the molten substance, and zone refining. There are instances in which impurities form eutectics with the host material that have higher melting points than the pure substance, so that it is good practice to reject the first crop of crystals as well as the last fraction of the melt. Fractional freezing has been used to purify many organic substances, often on a large scale, including benzene, substituted benzenes, and other aromatic compounds of relatively low molar mass.

Recrystallization from the melt is used to purify several organic compounds for use as reference materials and working standards. Column crystallization is the name given to the technique of filling a column (usually glass) with the molten substance to be purified, and then gradually lowering it into a cooling bath held at a temperature slightly below the expected melting point. Cooling is stopped before the material has fully solidified and the remaining melt is drained off. The technique of recrystallization from the melt has also been employed for the purification of a wide variety of organic compounds including benzoic acid, phenols, aromatic hydrocarbons, and higher aliphatic acids and alcohols. The technique gives the most satisfactory results on substances that are already substantially pure and is therefore often applied as the final stage of purification.

Zone refining or zone melting is a particular form of fractional crystallization applicable to any solid. The apparatus consists of a long tube with an annular heater that is arranged to pass very slowly along the tube (or in smaller devices through which the tube passes) so that a slowly traveling molten zone is created in the column of material. Several passages of the molten zone are made and impurities concentrate at the ends of the column. After the passage of several molten zones, the substance is allowed to cool and the ends containing the impurities are discarded.

The technique is carried out on quantities ranging from the semimicro, for laboratory investigations, to the macro commercial scale. It is used in the production of highest-purity silicon and semiconductors, single-crystal compounds of technical importance such as alkali metal halides, and for many organic compounds. As mentioned earlier, the technique works best for substances that are already fairly pure, and in the field of analytical reagents is particularly useful for converting analytical-grade substances into superpure grade for use as working and reference standards. Reagents and reference substances purified in this way include benzoic acid; alkali halides; naphthalene, anthracene, chrysene, and pyrene; morphine; dibenzyl and biphenyl; benzo-phenone; and 4-aminoacetanilide.

## Drying and Solvent Removal

A solvent is usually removed simply by heating the material at a temperature above the boiling point of the solvent. If heating to this temperature will cause decomposition of the substance, heating under vacuum is the next alternative. In cases where no heating can be used, the substance is sealed in an evacuated vessel containing a suitable absorbent; for example, sodium hydroxide pellets are suitable for removing acetic acid.

Drying can present particular problems. Inorganic substances are often hydrates and it is important not to over dry. These materials are usually left to equilibrate in a sealed vessel containing a suitable hygrostat, which is a strong aqueous solution having a known and suitable vapor pressure. Tables of hygrosats are available in the well-known chemical data books. Labile organic chemicals and biochemicals are freeze-dried under vacuum, and sometimes are allowed to just melt and then refrozen with the vacuum maintained throughout the cycle, which may be repeated as necessary.

The fractional distillation of organic liquids and the use of azeotropes to remove water has been mentioned earlier. In many instances, organic liquids may be dried directly by adding desiccants. Traces of water may be removed from some solvents by treatment with activated alumina or, on the laboratory scale, with sodium, sodium borohydride, or calcium hydride. Molecular sieves of type 4A, i.e., with a porosity of  $\sim 4 \text{ \AA}$ , are also extremely useful for the removal of water and a number of other small molecules from organic liquids.

Drying agents vary greatly in the intensity of their action, and their suitability to particular substances, especially with regard to any hazard and the likelihood of causing other contamination.

## Filtration

Filtration is employed to remove insoluble impurities from solutions and melts. The techniques of filtration of the laboratory and small manufacturing scales need not be repeated here. It is appropriate to remember the wide range of filtration media and aids that are now available and that filtration may be performed hot or cold and under temperature control. For the efficient removal of relatively small quantities of fine suspended matter, centrifugation provides a suitable approach.

All liquids contain vast numbers of submicrometer-sized particles that are too small to be visible but that can be detected and counted with high-sensitivity apparatus. Chemicals used on industrial processing of ultralarge-scale integration devices must be essentially free from these particles and suitable filtration membranes are available with porosities as low as  $0.01 \mu\text{m}$ . It is to be expected that use of these filters will make significant improvement to the chemical purity of the product. In acids and ammonia solution, many trace metal impurities are present in the form of submicrometer particles and ultrafiltration in a suitable clean environment is useful for improving reagents intended for trace analysis at levels of  $\mu\text{g}$  per kg and lower.

## Chemical Treatment

Solvent extraction is used for the separation of substances of different polarity and is employed in freeing organic liquids of inorganic impurities. Examples include the washing of acids from insoluble solvents with sodium carbonate solution and the purification of dithizone solutions by transferring its anionic form into dilute alkali solution, discarding the organic phase, and then reverting into fresh organic phase by acidification of the aqueous solution and extraction. It is also used to remove organic impurities such as grease from inorganic compounds, and generally for separating substances of sufficiently different solubilities. In the laboratory it is often employed to free reagent solutions of troublesome impurities; for example, those that could cause high blank values. This is usually combined with an appropriate chemical reaction. Thus, some reagents intended for use in a test for iron can be purified by pretreatment with 4,7-diphenyl-1,10-phenanthroline and solvent extraction to remove the complexed metal.

Precipitation has been used widely for selective purification in much the same way, but in the author's experience it is less useful because only substantial amounts of impurities give filterable precipitates, and so 'collectors' must be added.

In removing one impurity, therefore, the general purity of a reagent solution will be decreased.

Ion exchange is also used quite widely to purify reagent solutions, particularly to remove trace metals and sometimes anions. Alumina, for example, is a particularly effective anion exchanger for sulfate ion and removes it from acidic and neutral solutions.

Controlled-potential electrolysis has also been used for removing some metals from inorganic solutions, and reagents for use in voltammetry have been purified to remove traces of cadmium, copper, lead, nickel, and zinc.

It is sometimes possible to remove a metal such as copper from an inorganic solution by stirring in the presence of a more reactive metal such as zinc. The copper displaced from solution plates out on the surface of the zinc. An equivalent amount of zinc passes into solution, of course.

There are no useful guidelines for chemical processing because of the range of problems encountered, but a few examples will now be given of approaches that have been used. Lithium aluminum hydride is used to reduce traces of carbonyl compounds, including carboxylic acids and anhydrides, and peroxides to alcohols. It is also useful for reducing amides and nitriles to amines. Precautions must be taken when using the reagent, such as ensuring that the substance to be purified is dry and that reactions are conducted in the cold.

Sodium borohydride is less active but has the property of reducing aldehydes, ketones, and peroxides, and a number of other commonly encountered impurities. Aldehydes are eliminated from acetic acid and other lower monocarboxylic acids by refluxing with sodium or potassium dichromate solution and fractionation. Alcohols and esters for use as UV solvents may be treated with sodium borohydride or with 2,4-dinitrophenylhydrazine before distilling, to remove aldehydes and ketones.

Traces of nitric acid in hydrofluoric acid have been prevented from distilling by pretreatment with aluminum powder to reduce nitrate to ammonium, and

traces of sulfide in the same acid have been removed by oxidizing to sulfate with hydrogen peroxide before distillation.

### Introduction

Considering the huge variety of surviving archaeological artifacts and contexts, the range of scientific dating techniques available to the archaeologist is remarkably small. All are material specific and seldom (with the exception of dendrochronology) can an accuracy of better than a few hundred years be achieved. There are also some obvious lacunae: there is no method of dating the manufacture of purely metallic objects, or of the vast majority of lithics, and in such cases, archaeological dating depends on the traditional methods of stratigraphy and typology (the importance of which cannot be underestimated, but which do not fall within the remit of this article).

Even where material suitable for scientific dating is found, the event that can be dated may not have direct significance to artifacts or archaeology. Most scientific dating methods relate to material, not manufacture: only in a few cases like thermoluminescence is the age directly related to a point in a production process generated. For wood, for example, dates produced, whether by radiocarbon or dendrochronology, can only relate to the time at which the plant tissues present were formed, not when the tree was felled or used; seasoning, storage, reuse, or even deliberate use of old materials to deceive cannot be detected.

Equally, a sample can only be used to date an associated context or material if that association is real

and direct; if a context has been disturbed after formation, or if the sample is residual, as, for example, bone from an earlier midden included in the fill of a later ditch, the use of scientific dating methods, no matter how precise and accurate the measurements, has no realistic meaning. Despite all these caveats, the introduction of scientific dating methods into archaeology has had a revolutionary effect on our perceptions of the past, has provided us with a firm chronological framework, and, particularly in the case of radiocarbon, has led to major reevaluations of previously accepted chronologies.

This article is intended as a general introduction to some of the methods used. Radiocarbon is deliberately discussed in most detail as it is probably the most frequently exploited of the techniques. Many of the more general points made in the radiocarbon section do, however, relate equally to other dating methods.

### Requirements for a Functional Dating Technique

Devising a usable dating technique requires a characteristic that alters in a known fashion with time (usually by steady increase or decrease), the ability to measure that change, a means of deriving a clean sample unaltered in other ways, and a zeroing mechanism to effectively start the clock. Not surprisingly, most dating methods are dependant in some way on naturally occurring radioactivity, although there are a number of other mechanisms that have proved usable.

Besides those methods that give a fixed time point (with or without calibration by other means), there are some 'relative' methods that, whilst not yielding a real 'date', can give information on the sequence of events.

## Radiocarbon Dating

### Theory

Radiocarbon dating is possible because of the existence in nature of the radioactive isotope  $^{14}\text{C}$  (albeit in small quantities; the vast majority of natural carbon is composed of the stable isotopes  $^{13}\text{C}$  and  $^{12}\text{C}$ ). This isotope has the advantages for the study of the human past of a conveniently long half-life (of  $\sim 5730$  years, although by convention radiocarbon results are calculated on the 'Libby' half-life of 5568, the accepted figure at the time that the radiocarbon technique was devised; the necessary correction is made as part of the calibration process described below) and of the ubiquity of carbon throughout the biosphere. The theoretical basis of the method is illustrated schematically in Figure 1.  $^{14}\text{C}$  is formed in the upper atmosphere by the action of cosmic rays on  $^{14}\text{N}$ . The resultant  $^{14}\text{C}$  rapidly oxidizes to  $^{14}\text{CO}_2$  and is swept into the general carbon cycle, mixing rapidly and thoroughly throughout the atmosphere, and via photosynthesis and the food chain into the biosphere. There is also an exchange into bodies of water, notably the deep oceans, which hold the vast majority of the world's carbon, although oceanic carbon distribution is complex. In terrestrial contexts the consumption of plant material by animals ensures the rapid spread of  $^{14}\text{C}$  throughout living organisms. During life food consumption constantly replenishes the  $^{14}\text{C}$  lost by decay. On death, however, this replacement ceases and the level of  $^{14}\text{C}$  falls following the general formula for radioactive decay given in eqn [1]:

$$A = A_0 e^{-\lambda t} \quad [1]$$

where  $A$  and  $A_0$  are the present and original isotopic quantities, respectively,  $\lambda$  is the reciprocal of the mean life (the average lifetime of a  $^{14}\text{C}$  atom), and  $t$  is the elapsed time.

If it can be assumed that the rate of  $^{14}\text{C}$  production has not varied over time, and thus that a dynamic equilibrium has formed, and if it is possible to extract clean sample carbon, unaltered apart from the decline in  $^{14}\text{C}$ , and to measure its current  $^{14}\text{C}$  concentration, it is possible using eqn [1] to calculate the elapsed time since the death of the organism. In practice, the process is far more complicated than this brief description indicates. Principally, one of the basic assumptions, that the rate of  $^{14}\text{C}$  formation is constant, is known to be incorrect. The rate has, in fact, varied over time in response to a number of effects, principally fluctuations in the cosmic-ray flux with changes in the geomagnetic field and in solar activity. Because of this, no radiocarbon measurement equates directly with a calendar date, and all such measurements must be calibrated before use.

### Radiocarbon Calibration

Unfortunately, the temporal changes in  $^{14}\text{C}$  flux have been too complex for simple modeling and it has been necessary instead to find a way of making direct measurements. Dendrochronologically dated wood (see section below for an explanation of this procedure) has proved ideal for this purpose; the tissue of an individual tree ring stops exchanging carbon within a very short time of being formed, thus

Figure 1 Schematic depiction of the  $^{14}\text{C}$  cycle.

preserving a measure of the  $^{14}\text{C}$  concentration in that year. As discussed below, this can present difficulties in dating, but it has allowed the production of long graphs (usually termed calibration curves). Currently there are internationally agreed and accepted high-precision calibration curves, based on 10- and 20-year sections of ancient oak preserved in the peat bogs of Ireland and lowland Europe, back to 10 300 BP. This is further extended back to 24 000 BP by uranium/thorium dating (see below) of corals (although with considerably larger error terms). The calibration curve has proved to have two main characteristics; an overall, and apparently sinusoidal, curve (period  $\sim 9000$  years), with a large number of short-term variations (wiggles) superimposed. These wiggles are the main bugbear in the practical usage of radiocarbon as a dating method. They mean that a single radiocarbon measurement can calibrate to a calendar year range larger or smaller than the measurement precision, depending on the slope of the calibration plot at that precise period, and even that a single result can relate to two, or more, perfectly possible calendar age ranges.

While the original radiocarbon analysis has the Gaussian probability distribution typical of any such measurements, the necessity to calibrate it against a nonmonotonic graph destroys this property, producing a probability distribution of unpredictable, but always irregular, form. As a consequence, the application of most standard mathematical techniques to the calibrated date ranges is impossible. This problem, which once made radiocarbon data extremely difficult to fully exploit, has now been largely overcome by the use of Bayesian statistics. Use of this technique has permitted radiocarbon measurements to be easily modeled, compared and combined with each other, and with results from other dating methods.

In addition to cosmogenic  $^{14}\text{C}$  variations there are also two distinct readily recognizable anthropogenic variations in  $^{14}\text{C}$  level, at the most recent end of the curve. These are the fossil fuel effect, a rapid lowering of atmospheric  $^{14}\text{C}$  levels at the end of the nineteenth century, due to the widespread burning of fossil fuels which released 'old' carbon depleted in  $^{14}\text{C}$  into the atmosphere; and the bomb effect, a massive increase in  $^{14}\text{C}$  in the 1960s following the atmospheric testing of nuclear weapons. Both have implications for radiocarbon dating, with the fossil fuel effect making precise dating of much of the last two centuries impossible. The bomb effect has had at least one positive side-effect; the resultant spike has been widely used as an isotopic marker, allowing the dynamics of the carbon cycle to be more readily explored.

## Measurement Techniques and Sample Sizes

Until the 1980s, measurement of  $^{14}\text{C}$  activity could only be made by decay counting (usually termed conventional dating), in either gas proportional or liquid scintillation counters, necessitating the use of large samples (of  $\sim 4$  g of elemental carbon, and commensurately higher weights of raw material), but more recently the use of accelerator mass spectrometry (AMS) has permitted the direct measurement of  $^{14}\text{C}$  ions and has led to a dramatic decline in sample size to 3 mg or less, thus greatly extending the range of materials which can be dated.

Since all the counting methods involve the conversion of sample carbon to suitable chemical forms (usually methane or carbon dioxide for gas counting, benzene for liquid scintillation, and graphite or carbon dioxide for AMS), the method is always destructive. Additionally, extensive cleaning of the sample is always required to remove extraneous carbon. Fortunately, most radiocarbon samples are either of wood or charcoal, both of which are remarkably stable and do not exchange carbon with their surroundings, although a prolonged residency in the soil will obviously result in an amount of intrusive material. Bone presents more of a problem as the inorganic component (mainly hydroxyapatite) is not a closed system and is liable to isotopic exchange, particularly with groundwater. For this reason only the organic (protein) component of bone, mostly present as collagen, is analyzed. The advent of AMS has allowed more specific fractions, down to individual amino acids, to be extracted and dated. The inorganic fraction of shell is subject to a similar exchange, but here there are further complications as both terrestrial and marine mollusca are capable of directly reworking geological carbonates, and marine samples are subject to the marine effect discussed below.

Chemical methods are available to cope with most natural contaminants, but the use of some modern materials, particularly of petroleum-derived coatings as consolidants, can destroy the integrity of materials as radiocarbon samples.

## Sample Materials

Although in theory it is possible to date the death of any living organism by radiocarbon, there are a number of practical limitations on the materials that can be meaningfully analyzed. Firstly, as with all dating techniques, there is the question of sheer durability; it is only possible to date those materials that have survived from antiquity. These seldom include soft tissue, or the more transitory plant fibers, and even given the extended range of sample types

allowed by the small sample requirements of AMS, ~90% of archaeological radiocarbon samples are wood, charcoal, or bone.

Equally important, but frequently overlooked, is the necessity to analyze only materials where the time of cessation of carbon exchange relates in some way to an archaeological event. The most obvious example of the dangers involved here relates to wood. As already discussed, the tissues of individual tree rings cease to exchange carbon within a few years of their formation. This has been invaluable for the production of calibration curves, but is an enormous problem in practical dating terms. The majority of archaeological recovered wood or charcoal comes from mature trees. For long-lived species, such materials can have an apparent age of several hundred years ( $1000 +$  years for European yew) even before felling. Moreover, the potential offset between the date measured by radiocarbon and the actual date of use can be huge, and more importantly unquantifiable. The only answer is to avoid the problem by identifying all woods before dating and only analyzing young roundwood or short-lived species.

Obviously there are occasions where this is impossible, particularly where the question is the date of a wooden object. All that can be hoped for is a *terminus post quem*, an oldest possible date, before which the object cannot have existed. An offset also occurs with marine materials. Here, because of the time taken for atmospheric carbon dioxide to absorb into ocean waters, and poor oceanic mixing, all marine organisms, and all animals dependant on marine sources for food (including whale and walrus, both frequently exploited for raw material), are subject to an age offset in the region of a few hundred years that varies with exact location, making it effectively unquantifiable. Hence, precise dating of the purported medieval whalebone plaque illustrated in **Figure 2** is impossible. An AMS date on a small sample measured at the Oxford laboratory gave an uncalibrated figure of  $1480 \pm 80$  BP (OxA-1164). Adding the expected marine offset of a few hundred years gives a final result in accord with the style, although this figure can only relate to the whalebone itself; the possibility still remains that old material was used for a more carving.

### Age Range

The maximum age definable by radiocarbon depends on minimum measurement levels. Using conventional techniques this was limited to around eight half-lives, extended to ~60 000 years by enrichment techniques. With the advent of AMS it was hoped to extend this to 70 000 or 80 000 years, but such figures have yet to be routinely obtained. Minimum age is complicated to define; the fossil fuel effect means that

**Figure 2** Purportedly medieval Spanish whalebone plaque. (© Trustees of the British Museum).

results for the past 200 years are virtually indistinguishable, and such results are quoted as modern by convention. However, the bomb effect makes the years immediately after 1950 easily identifiable. Precision varies both with measurement error and with the shape of the calibration curve. The so-called high-precision measurements can give results with error terms of  $\pm 18$  radiocarbon years or less, whilst results for full-sized samples measured to normal precision will give figures of  $\sim \pm 40$  years for the past 10 000 years, with the error term increasing slightly for older materials or for less than ideal sample sizes. What these error terms equate to in real calendar years is entirely dependant on the shape of the calibration curve at the period in question.

### Radiocarbon Conventions

The presentation of radiocarbon measurements has been rigidly formalized. All measurements are made relative to a 'modern' standard of oxalic acid, the activity of which has been related to the theoretical

activity of wood of AD 1950 had no fossil fuel effect occurred. Measurements are quoted in years BP, with present fixed at AD 1950, with an error term equal to  $\pm 1\sigma$ , and using the Libby half-life of 5568 years. Calibrated results are quoted as cal AD or cal BC as appropriate, with the confidence level noted. There are few such formalized rules for the formulation of results by other dating techniques, and individual publications have to be consulted for such details.

### Case Studies

Practical use of  $^{14}\text{C}$  is best illustrated with some examples. Probably the most publicized recent case has been the dating of the Turin Shroud, a length of linen bearing the shadowy imprint of a man, believed by many to be the shroud of Christ. Independent analysis of small samples of the linen of the shroud by three AMS dating laboratories produced concordant results, with the weighted mean calibrating to a possible calendar date range of 1260–1390 cal AD (at the 68% confidence level), which ties in closely with the first known historical appearance of the object in ca. AD 1350. Given the contentious nature of the material, it is not surprising that there has been some controversy about this result, but the scientific evidence certainly indicates the linen to be medieval.

More typical is a project run by English Heritage to securely date the various phases of activity at Stonehenge, a massive megalithic monument in Southern England. This site has long been acknowledged to be complex and multiperiod, with probable origins in the Neolithic, but the actual sequence of construction has been far from clear. Here, 52 radiocarbon determinations were measured to date the three phases of the site itself, plus pre- and postmonument use of the area. The dating of Phase 1, the cutting of the main ditches and banks, was made easier by the presence of large numbers of tools made from the antler of red deer, used during the construction work, in the base of the ditches themselves. Many of these came from slaughtered animals rather than being naturally shed, and can therefore be expected to date to within a few years of ditch construction. It was more difficult to obtain samples directly related to other phases (particularly the construction of the main stone circles), but nonetheless a combination of radiocarbon measurements and Bayesian statistical analysis has produced a definitive chronology for this important site.

## Luminescence Dating

### Theory

There are two forms of luminescence dating of importance to archaeology; thermoluminescence (TL)

dating and optically stimulated luminescence (OSL) dating. TL was the earliest to be widely used, although OSL is rapidly gaining in importance. Both methods are dependant on the damage done to some nonconducting crystalline materials (notably quartz and feldspar) by naturally produced ionizing radiation, although in neither case is the process fully understood. The theory behind the techniques is probably most easily explained in terms of TL.

Thermoluminescence is the light emitted in addition to the normal incandescent glow when some crystalline materials are heated. Although the process is in reality much more complex, it is most conveniently explained in terms of a simplified model involving 'traps', small imperfections in the crystal lattice. When the crystal is exposed to ionizing radiation, electrons are released. Most of these will recombine almost immediately, but some fall into traps, where they remain until sufficient energy is input to release them. The depth of the trap (i.e., the energy required to escape from it) varies, but can be substantial, equivalent to a long electron residence period at ambient temperatures. It is usually these relatively stable traps that are used for dating purposes. On release the electrons can take several paths, one of which is to recombine with an ion within the structure. If this occurs at a specific type of defect (a luminescence center) light (i.e., the TL) is emitted. Since the number of trapped electrons is proportional to the exposure of the material to ionizing radiation, and the TL is proportional to the number of electrons released, if the material has since been exposed to a measurable and constant radiation flux it is possible to relate TL directly to the time since the traps were last emptied. If the date of this clearing of the traps has some archaeological significance, it is possible to use this property as a meaningful dating technique. In the case of TL dating, emptying of the traps is caused by heating (most commonly when clay is fired to produce ceramic). After zeroing, the material will be exposed to radiation from naturally occurring uranium, thorium, and potassium ( $^{40}\text{K}$ ) present in the sample itself and its surroundings. The concentrations of these isotopes are highly variable, so that values must be determined separately for each sample and context, but all are very long-lived, and providing the material has remained in the same environment, the radiation flux can be treated as being constant. It is therefore possible to use eqn [2]:

$$\text{Age} = \frac{\text{Archaeological TL}}{\text{Annual dose} \times \text{TL per unit dose}} \quad [2]$$

where archaeological TL is the naturally accumulated TL, annual dose is the annual dose rate to which

the sample has been exposed, and TL per unit dose is the sensitivity of the sample material to that radiation.

There are many complications to the method, including the anomalous fading exhibited by some materials and the variability of response by different materials, which means that the individual sensitivity of each sample to radiation must be determined. A number of different measurement techniques, involving the use of different fractions of the sample, have therefore been developed; the measuring laboratory will select the most appropriate.

The theory underlying OSL dating is analogous to that of TL, but here the zeroing process is the exposure of fine soil particles to light. This means it is most useful when looking at sediments which have been bleached by sunlight during deposition, and which relate to an archaeological event in some way (such as the first soil deposited in a ditch).

### **Sample Materials**

In archaeological contexts TL is most commonly used to date the firing of ceramics (including the clay cores sometimes found in metal castings) and burnt stone (particularly flint). OSL is used mostly to date sediment deposits.

### **Dose Determination**

The radiation dose received from the environment is determined by onsite measurement either with a gamma-spectrometer or by burying capsules of a highly sensitive material (usually calcium fluoride) for a known period. The radiation dose from the material itself (the internal dose) is found by direct measurements of the portions of the samples. For situations where the find spot is not known, or where ceramics have been constantly used and never buried, the environmental dose rate can only be estimated. This is obviously subject to a much greater error, and such measurements are a form of authenticity testing rather than dating.

### **Age Range**

The age range for which TL can be used depends on specific characteristics of sample sensitivity and environment; for ceramics the lower limit can be a few hundred years, whilst for flint it is seldom possible to date anything younger than a few thousand years. The upper limit is also variable, depending on the point at which all the available traps are filled (saturation), and on the stability of the traps, but ages of 100 000–500 000 years should be possible. Precision depends on exact circumstances but can be as good as  $\sim \pm 5\text{--}10\%$  of the age for dating and

$\pm 25\%$  for authenticity testing, where the environmental dose-rate is estimated.

The age range for OSL is again dependant heavily on site conditions, but is basically similar, as is the precision, although new measurement methods, involving the use of lasers, can give precision as good as  $\pm 1.5\%$  for young ( $< 2000$  years) sites, and multiple sampling can allow the resolution of events on the scale of a few decades for the last 100 000 years.

### **Case Studies**

An example of the use of TL as a dating method is provided by the excavations at Pontnewydd Cave in north Wales, where despite the difficulties caused by variations in the environmental dose rate because of the nature of the deposits, TL has established an early hominid occupation  $\sim 200\,000$  years ago.

OSL has been used to at least partially solve one of the continuing questions of British archaeology; the age of the hill figures cut into the chalk hillsides of Britain. The White Horse of Uffington is one such figure, dated variously to the Iron Age, Roman occupation, or later. Excavation of the figure has proved that, rather than being manufactured by simply clearing areas of the chalk surface, trenches were dug and chalk packed into them to form the lines. Silt from the earliest of these has been dated by OSL to 1400–600 BC, placing the figure firmly in the late Bronze Age.

### **Electron Spin Resonance**

A related dating technique is electron spin resonance (ESR) where the presence of trapped electrons is detected by their response to electromagnetic radiation. ESR is particularly useful as it can be applied to a complementary range of materials, including tooth enamel and shell, which decompose on heating and are therefore not suitable for TL work.

### **Dendrochronology**

Dendrochronology, or tree-ring dating, as implied by the name, is only applicable to timber. It exploits the characteristic of certain species of tree (notably oak and pine) of producing annual rings the width of which varies with local weather and water supply conditions. These patterns of rings can be compiled by cross-matching measurements from trees of known felling date, backwards through time, with wood from other sources, such as building timbers, to build up master curves of ring width pattern against age, as illustrated in **Figure 3**. Samples of unknown date can then be dated by comparison with

**Figure 3** Schematic demonstration of the construction of a dendrochronological master curve.

this master. Such curves are normally specific to species and to region, although there has been some limited success with interspecies cross-dating.

Where material from a site with extensive timber survival cannot be tied directly to one of the existing master chronologies, it is sometimes possible to construct a 'floating' chronology that can be used as a relative dating tool. There are a few periods where the growth ring pattern is so distinctive as to produce a 'signature', almost instantly datable on the basis of a small number of rings, but for the most part dendrochronology requires large samples (90+ rings). Even given this amount of material, and a suitable local master curve, the method is not always successful, but where it is it yields a very precise date, giving not only the exact year, but even the season of growth of the outermost ring present.

In real terms, this apparent precision may not mean much; the figure can only apply to the outermost ring present, which is not necessarily the original surface of the tree. In fact, in most circumstances, the more vulnerable sapwood at least will have been trimmed before use. In building timbers it is frequently only this layer which is removed, leaving the 'waney edge', the boundary between sapwood and heartwood. There are well-defined formulae for the numbers of sapwood rings in different species, which can be applied as a correction if the waney edge is present, but if it is absent it is impossible to quantify how many years of growth have been lost.

In addition, as with radiocarbon, dendrochronology can only date the formation of the wood, not its use. A dendro date gives at best the year of felling. It can give no indication of time elapsed in

seasoning, storage, or possible repeated reuse (a frequent event with large timbers). Furthermore, any self-respecting forger will select wood of a suitable age as a raw material.

Dating is possible over the whole calendar range for which master curves are available, but the size of sample required means that the method is seldom applied to samples more than a few thousand years old.

Another important property of the long dendrochronological curves now available (see section on radiocarbon for details) is that they provide a proxy climatic record for their region; whilst not always easy to interpret, they do give direct evidence of the nature of climatic change over time for thousands of years.

## Decay Series Dating (Other than Radiocarbon)

These methods relate, in general, to the formation of geological deposits, and are seldom of direct use in archaeology. They do serve, however, as a means of defining time periods, for example, for strata trapped between lava flows, and play an important part in the understanding of early man.

### Potassium–Argon/Argon–Argon Dating

The weakly radioactive  $^{40}\text{K}$ , naturally present in most of the earth's crust, decays to two daughters,  $^{40}\text{Ar}$  and  $^{40}\text{Ca}$ , with a half-life of 1250 million years.  $^{40}\text{Ar}$  is insoluble in molten rock giving a zeroing mechanism for lava flows. After resolidification of the rock, argon gas generated can be trapped within the glassy matrix. Given a closed system, collection and measurement (by mass spectrometry) of trapped  $^{40}\text{Ar}$  can therefore be used to date the formation of the lava flow. The long half-life and minute original quantities of potassium mean that the method is fairly imprecise (with error terms ranging approximately from  $\pm 1000$  to  $\pm 10\,000$  years depending on age), but it does extend far back into geological history. A variation on this technique,  $^{40}\text{Ar}/^{39}\text{Ar}$  dating, involves the artificial generation of  $^{39}\text{Ar}$  from the stable  $^{39}\text{K}$  by neutron irradiation. Potassium concentration can then be determined by measurement of the  $^{39}\text{Ar}$ . This has the advantage of requiring only one measurement procedure, of the isotopic ratios of argon, but more importantly allows a controlled release of argon by gradual temperature increase, which can be used to detect sample contamination. In an uncontaminated sample the  $^{40}\text{Ar}/^{39}\text{Ar}$  ratio will remain a constant; any variation demonstrates a problem with the sample, due either to a partial

reheating postformation releasing some argon gas, or the presence of atmospheric argon that survived the initial melting.

### **Uranium Series Dating**

Uranium series dating utilizes the two natural uranium decay chains (from parent  $^{238}\text{U}$  and  $^{235}\text{U}$ ) and their progeny. The zeroing process here is usually the formation of calcite from carbonates (with uranium present as an impurity) carried in solution. Since the primary long-lived daughter,  $^{230}\text{Th}$ , is largely water insoluble, in any process involving dissolution and redeposition of uranium there will be effectively no thorium present in the newly formed crystal matrix, and, provided the system remains closed, the proportions of generated thorium and other daughters can be used as a clock. The method is most frequently applied to geological formations of calcite (spellotherms or travertine) but has occasionally been applied to deposition of calcite within fossil bone, although with limited success owing to variation in uranium uptake and the open nature of the system.

Age ranges and precision vary with uranium content of each sample, but in general the method can cover a period between 1000 and 100 000 years BP to error limits of  $\sim \pm 1\%$  of age.

## **Other Dating Techniques**

### **Amino Acid Racemization**

It is possible for asymmetric compounds to exist in two mirror image but nonsuperimposable forms, known as optical isomers. The amino acids that build up proteins are invariably formed in living tissue as only one form, the L-isomer. After formation, a slow racemization process begins in which the L-form is converted to the alternative D-form, until a dynamic equilibrium is reached in which the amounts of the two forms are equal. Provided that the equilibrium point has not been reached, the portion of the D-form present can be used as an indication of age. The rate of conversion is heavily dependant on a number of factors, principally temperature, humidity level, and degree of chemical breakdown of the tissue involved (diagenesis).

Amino acid dating has been applied with varying degrees of success; because the rate constant varies so much with local conditions, it can only be determined by calibration using similar materials from the same area, dated by other independent means. The assumption has to be made that both sample and calibration material have been subjected to the same conditions (for example, boiling of bone will

radically alter the rate constant for that time) and there have been some heavily publicized incorrect ages generated as a result of wrongly estimated rate constants, notably with regard to the first human occupation of the Americas. Despite these drawbacks, the method, which requires sample sizes of less than 1 g, can be useful.

The timescale that can be covered depends on the amino acid used and the environmental conditions, but ages in excess of 50 000 years are certainly theoretically possible. Precision is heavily dependant on that of the calibration results and no general figures can be quoted.

### **Obsidian Hydration**

This technique is only applicable to the volcanic glass obsidian, and depends on measuring the thickness of the opaque hydration layer that slowly develops on any fresh surface. As this is a diffusion process, the rate is heavily dependant on temperature and results must be calibrated for particular areas using dates determined by other methods, making estimates of precision impossible to generalize. Efforts have been made to apply similar procedures to surface change on other lithics and on glasses, but never with the same degree of success.

### **Archaeomagnetism**

It is well known, even if the process is not well understood, that there have been extensive temporal changes in both the strength and direction of the earth's magnetic field (including occasional total polarity reversal). Most clays and soils contain a small percentage of finely dispersed particles of iron oxide. These grains are small and frequently have a single magnetic axis. In raw clay these particles are randomly aligned, but on firing above a critical temperature (the blocking temperature) some acquire sufficient energy to adjust direction to that closest to the external magnetic field, hence producing a very small but permanent thermoremanent magnetism with an intensity proportional to that of the current geomagnetic field, and in the same direction. This property is only useful as a means of dating if the sample is found *in situ* (so that the original magnetic direction can be determined) and if there is an existing reference graph of changes in field direction and strength against time for the locality, dated by other means.

Large samples are required, in the form of blocks of baked material several cubic centimeters, but as the method is useful mainly for dating kilns and hearths this is seldom a problem. Sedimentation processes can produce a similar remnant magnetism,

although with a field strength an order of magnitude less, which can be used for dating provided there has been no postdepositional disturbance.

Precision is highly variable, depending on the rapidity of field change and on the precision of the calibration samples.

## Selection of a Suitable Dating Technique

In general, the constraints of methods and materials are such that there is little conflict about dating methods. The preferred technique will depend on the context, the materials available, and the prospective error term with each method. For many sites the ideal answer will be a combination of methods, followed by the use of Bayesian statistical techniques to analyze the results.

## Metallic and Ceramic Objects

**L T Gibson**, University of Strathclyde, Glasgow, UK

## Introduction

The application of scientific knowledge and the use of analytical techniques have been implemented in archaeometric and conservation science researches for many years. Specimens are often subjected to analytical scrutiny to help provide a fundamental understanding of the materials used in the production of ancient objects, and to assess the stability of artifacts. The goal is to inform our generation of past technologies, social history, and to ensure the continued protection of items important to our cultural heritage. Each year many hundreds (if not thousands) of research papers report the results of archaeological and conservation research that utilize modern analytical instruments. The numbers of articles increase each year, and as such it is impossible to list all areas of research in this short section. Therefore, the main aim of this article is to describe, briefly, some of the many analytical techniques currently used (1) in the archaeological study of metals and ceramics, (2) in the conservation and restoration of metals and ceramics, and (3) to identify corrosion and/or deterioration products.

## Archaeological Examination of Metallic and Ceramic Specimens

Metals and ceramics are the focus of archaeological research as they are often thought to be among the most rudimentary substances in humanity's technological and social development. There are many reasons to initiate archaeological research; however, it can be argued that the main aims of study of metallic and ceramic specimens are to determine their origin, authenticity, and function, and to explore past manufacturing processes. Perhaps the largest single reason for the study of these specimens is to ascertain their provenance (the geographic origin of the raw materials used). The data obtained from provenance studies are used to identify the raw materials used during production, to date and/or authenticate specimens, and to provide information about ancient trading patterns. The basic premise in provenance determination is that each material source can be distinguished by its chemical composition. Consequently, one of the major applications of analytical science to archaeology has been to determine the major, minor, and trace element composition of archaeological specimens. Coupled with the analysis is the need for the analytical scientist to interpret the analytical data correctly. Difficulties associated with this task should not be underestimated, as imitations

of recognized ceramics can cause subtle problems in provenance studies. Moreover, archaeometallurgists note that chemical provenancing of metal specimens can only be achieved when factors such as the addition or contamination of trace elements in metal alloys, and the high temperatures and extreme redox conditions used when processing the ores, are considered. Indeed, analytical interpretation can be further complicated if the composition of the surfaces of specimens are altered as a result of chemical weathering, corrosion, restoration or previous treatments.

## **Conservation of Metals and Ceramics**

When archaeological specimens are buried, it is not uncommon for a stable equilibrium to be established between the specimens and their surroundings. After excavation, many specimens rapidly deteriorate as a result of disturbing their equilibrium conditions. Conservators, and conservation scientists, examine artifacts to assess their stability, or to restore materials that have undergone, or are likely to undergo, a chemical or physical change. Clearly, the analytical scientist examining the specimen must have some knowledge of the types of material under study and be able to recognize known, stable specimen compositions.

After excavation and study, it is common to house ceramic and metallic specimens in museums, or to ensure appropriate environments are created to store or display specimens. Here, the goal is longevity, in other words, to safeguard specimens for future generations. This is a formidable challenge as all materials degrade naturally and at best we can only hope to prolong the lifetime of such specimens. The rate of change of materials can be slow (over hundreds of years), or indeed it can be very rapid (changes have been observed on metallic and ceramic surfaces over a matter of months). The surfaces of specimens commonly undergo significant chemical and physical alterations as a result of exposure to pollution and to changes in environmental factors such as light, temperature, and relative humidity. The synergistic effects of such factors are often very difficult to predict, and the chemical processes invoked, or exacerbated, on the surfaces of materials are difficult to elucidate. For example, a rather insidious problem has been observed when storing metals and ceramics in certain wooden cabinets or drawers. Acids and aldehydes (carbonyl pollutants) emitted from the materials used to make the furniture are known to react with the surface of ceramic and metal specimens. Since the first documented report of carbonyl pollution-induced deterioration on shells in 1899, a wide range

of multifarious, complex corrosion products have been observed on thousands of metal and calcareous specimens. Efflorescences of various compositions have been observed, and identified, on porous ceramics, and complex corrosion crusts have formed on the surface of metals such as lead, copper, and bronze. Analytical science has a tremendous role to play when attempting to understand the mechanisms of deterioration of such specimens. First, the deterioration product has to be identified before the chemical deterioration processes can be elucidated. Preventive conservation strategies are also implemented to examine the stability of materials and their surrounding environmental conditions in a bid to retard further decay.

Analytical investigations also focus on new ways of protecting susceptible materials that have not yet shown signs of degradation. The continued efforts to replicate archaeological artifacts and antiques and subject them to accelerated deterioration experiments provide useful results in the development of new treatments. Much can be learned from understanding how compositions deteriorate due to their inherent incompatibility or instability to external agents.

## **Instrumental Considerations**

As outlined above, there are a number of difficulties associated with the analysis of archaeological specimens. In summary, many specimens are:

1. unique or valuable, hence the analysis needs to be nondestructive or the sample taken from the specimen needs to be extremely small;
2. inherently inhomogeneous and the surface of the materials can differ substantially from their bulk compositions (for example, if they are glazed or decorated);
3. unstable due to removal from their burial environment; and
4. deteriorated or corroded.

As a result, a compliment of techniques will often be chosen to obtain solutions to the questions posed by archaeologists or conservators. The choice of instruments used should be assessed on a case-by-case basis, considering factors such as the amount of sample preparation required, cost and availability of instrumentation, sample size availability, complexity and sensitivity of instrumentation, and the ability to perform nondestructive testing.

The mode of analysis must also be considered. Qualitative analysis is performed to provide chemical information about the elements or compounds contained in a specimen whereas quantitative analysis

permits determination of the exact concentration of analytes in a sample. Should quantitative information be required standard reference materials should be prepared, or need to be commercially available, to calibrate instruments. Matrix matching between standards and samples should be encouraged, where possible, to prevent matrix interferences during analysis. However, this can be difficult when specimens of unknown origin and composition are examined. The need for a high level of accuracy and precision in the analytical method is a prerequisite, especially in provenance studies when sources of materials are distinguished from one another by examination of trace elements. The introduction of an artificial spread of data by using a technique with poor precision must be avoided.

Interestingly, much of the debate about the 'best' analytical technique to employ, and also the most appropriate chemometric approach to be used on the data is fruitless if the analytical scientist does not consider the data in the context of the archaeological or conservation questions to be answered. To solve complex problems in this area of research collaboration between analytical scientists, archaeologists, conservators, restorers, and art historians is crucial.

## Instrumental Techniques

It is perhaps not a surprise to learn that most modern analytical instruments have their place in archaeometric and/or conservation research. Many techniques are used extensively to study ceramic and metallic specimens or to identify pitting, weathering crusts, inclusions, efflorescence, and corrosion products on the surface of samples taken from specimens. In addition, the homogeneity of materials of mixed composition is examined, the results of previous restorations are assessed, and the major, minor, and trace element compositions of samples are recorded. A selection of instruments commonly used in archaeology and conservation research is given below. Detailed descriptions of the instruments can be found in the relevant articles in this encyclopedia.

## Visual Examination of Surface Topography

### Optical Microscopy

The optical microscope is the primary analytical technique of conservators and archaeologists to investigate surface topography, and to assess deterioration products of ceramic and metallic specimens. Although not a sophisticated analytical technique,

the optical microscope is widely available in museum and conservation laboratories. Automatic scanning interference microscopes (for example, Nomarski interference microscopy) are also used to obtain surface maps when estimations of the vertical height differences of surface features are required.

### Scanning Electron Microscopy

The use of electrons instead of a light source provides much higher magnification ( $>10\,000\times$ ) of specimens, unique imaging, and the opportunity to perform elemental analysis and phase identification. Scanning electron microscope (SEM), which provides a maximum lateral resolution of 10 nm, is used extensively to examine closely spaced topographical features of metallic and ceramic samples. The increased depth of field allows a large amount of the sample to be in focus at any one time, thus several areas of a sample can be examined without alteration of the field of view. Weathered and unaltered areas of a surface can be compared in one sample. Its main disadvantage is that samples are required for analysis and ceramic materials need to be coated to prevent charging. However, the combination of high magnification and resolution together with the large depth of field make it possible to study samples less than 0.1 mm in size.

### Environmental Scanning Electron Microscopy

When surface coating of ceramic materials is not appropriate environmental scanning electron microscope (ESEM) can be used. Whereas conventional scanning electron microscopy requires a relatively high vacuum in the specimen chamber to prevent atmospheric interference with primary or secondary electrons, an ESEM instrument uses a thin membrane to separate the specimen chamber from the vacuum system. Thus, nonconducting samples can be analyzed without charging, and hydrated specimens can be analyzed without fear of dehydration in the vacuum.

## Elemental Determination of Surfaces by Electron Beam Methods

### Energy Dispersive Spectroscopy

Elemental analysis of surfaces in SEM is performed using energy dispersive spectroscopy (EDS), which measures the energy and intensity distribution of X-ray signals generated by the electron beam striking the surface of the specimen. The elemental composition at a point, along a line, or in a defined area, can be easily determined to a high degree of precision. Elemental maps are often used to locate

areas rich in elements present in concentrations greater than 1% by weight. The electrons penetrate a depth of 0.02–1.0  $\mu\text{m}$  into the sample and so care must be taken to prepare samples appropriately if information about the bulk is required. EDS is used extensively for examination of metallic and ceramic specimens, and their associated weathering crusts or corrosion products.

### **Electron Probe Microanalysis**

Electron probe microanalysis (EPMA) (also known as wavelength-dispersive electron microprobe analysis) is used in the analysis of artifact composition; this technique is similar to X-ray fluorescence (see below) and is useful for studying small changes in composition within the body of an artifact as the penetration depth is up to 5  $\mu\text{m}$ . Excellent qualitative or quantitative determination of elements can be obtained with an atomic number greater than 5, although instruments that can detect elements only above oxygen are common in conservation laboratories. Lower detection limits (down to 100  $\text{mg kg}^{-1}$ ) than EDS can be achieved by EPMA, which can detect minor and trace elements in a sample. Standards can be used to obtain quantitative information. Samples prepared for analysis are generally flat, and the microprobe analyzer is designed to allow small amount of  $x$  and  $y$  translation rather than the full specimen manipulation that is typical of SEM (for example, full rotation and tilt). It is extremely useful for identification of elements in metallic or ceramic specimens, and to examine elements used to color, opacify, and clarify glass. Care must be taken with the analysis of glasses as the beam can heat the sample and cause the migration of alkali ions at the surface of the glass. As with EDS, the process is nondestructive for metallic samples, although nonconducting materials need to be coated and prepared as polished sections before insertion into the vacuum.

### **Auger Electron Spectrometry**

Auger electron spectrometry (AES) is not used as widely as SEM–EDS or EPMA. It has a limited use in the field of archaeology and conservation, possibly due to the limited penetration depth of the sample (less than 100  $\text{\AA}$  is not unusual), although research has been successfully undertaken with glass specimens. The sample (maximum size  $\sim 18 \text{ mm} \times 12 \text{ mm}$ ) can be scanned to survey the elemental composition of the analyzed surface, or to quantify elements present to detection limits of 0.1%. The lateral distribution of elements on the surface can be resolved to 0.3  $\mu\text{m}$ .

## **Elemental Determination of Surfaces by X-Ray Methods**

### **X-Ray Fluorescence Spectrometry**

The composition of a specimen is often determined by X-ray fluorescence (XRF) spectrometry, which performs rapid, qualitative, and semiquantitative determination of major and minor surface elements. Although both wavelength- and energy-dispersive (ED) analyzers can be used to detect the secondary X-rays, ED-XRF instruments are more common for the compositional determination of archaeological and conservation samples. Detection limits of  $\sim 0.1\%$  are expected; therefore, the analysis is difficult for trace elements. A laboratory XRF system, commonly used to quantify elements in metal and ceramic samples (noninsulating materials need to be coated), is considered to be an indispensable tool. As with all these surface analytical techniques, care has to be taken that weathering products (thick patinas or corrosion crusts) do not obscure bulk analysis results. Thus, samples are normally prepared to provide a flat polished surface to produce quantitative results.

Whole objects can be analyzed at ambient conditions using either a radioactive source (used for field investigations) or an X-ray tube. The advantage of the radioactive source is that it reduces the overall weight of the instrument, but the sensitivity is relatively poor due to the low photon output of the source. Legislation also restricts the transport of radioactive sources. In contrast, an instrument utilizing an X-ray tube as the source has found much greater use in conservation as the sensitivity is increased by an order of magnitude. This set up is commonly used for the analysis of whole archaeological objects, although care must be taken as radiation burns have been observed, and lead-containing glass has been known to discolor.

### **X-Ray Photoelectron Spectrometry**

X-ray photoelectron spectrometry (XPS) is used to determine major and minor element compositions of metallic and ceramic surfaces. It can also be used to determine the oxidation states of ions on the surface of a sample. However, it has a limited depth penetration of 2–20 atomic layers and so the measurements taken will be greatly influenced by the method of sample preparation. The ability to characterize elements with atomic numbers less than 10, coupled with the ability to analyze samples smaller than 1.5  $\text{cm}^2$ , make this technique particularly useful for the colorants and clarifying agents used in glasses and ceramics. For example, it has been used to

identify the oxidation states of copper on blue color Egyptian glass.

## Elemental Determination of Surfaces and Bulk Materials by Particle Methods

### Particle-Induced X-Ray Emission

Particle-induced X-ray emission (PIXE) is a technique that induces characteristic XRF by bombarding the surface of the sample with photons or helium ions. As a result of its low detection limits (between 1 and 100 ppm) for samples weights of a few milligrams, and the higher sensitivity obtained compared to XRF, PIXE is used to detect trace elements as well as major and minor elements. Thus, it is a technique of great importance in provenance studies. Indeed, it is often described as one of the most powerful methods for identifying the technology processes in archaeometallurgical investigations. Normally, samples are placed in a vacuum chamber and most instruments can accommodate samples sizes up to 3 mm<sup>2</sup>. Further advantages of this technique are that the instrument can be modified, separating the vacuum system from the sample chamber, permitting examination of specimens without sampling or charging. The penetration depth is ~10 µm, and as such it can indicate the bulk sample composition if surfaces are polished to remove tarnish, patinas, or weathering crusts prior to analysis. However, ion beams produced by accelerators in PIXE are expensive, and thus there are limited instruments available in conservation laboratories.

### Neutron Activation Analysis

Neutron activation analysis (NAA) is an important technique for performing both qualitative and quantitative multielement analysis of major, minor, and trace elements in the surfaces and interiors of a sample. For many elements NAA offers sensitivities that are superior to those attainable by other methods, on the order of parts per billion or better. In this technique neutrons interact with the target nucleus via a nonelastic collision, and a compound nucleus forms in an excited state. The excitation energy of the compound nucleus, due to the binding energy of the neutron with the nucleus, will be lost almost instantaneously as it de-excites to a more stable configuration through emission of one or more characteristic prompt gamma rays. In many cases, this new configuration yields a radioactive nucleus that also de-excites (or decays) by emission of one or more characteristic delayed gamma rays, but at a

much slower rate according to the unique half-life of the radioactive nucleus. The process is nondestructive (although the tube placed into the reactor only has a diameter of ~5 cm), if radiation times are chosen carefully so that samples do not remain radioactive for long periods of time. Further advantages of this technique are that minimal sample preparation is required and very small samples can be examined to obtain low detection limits. One disadvantage is perhaps accessibility as nuclear research reactors are required. Despite this, NAA is frequently applied to study the provenance, colorants, and opacifying agents in glass and ceramics, and metal specimens.

### Secondary Ion Mass Spectrometry

The ultrahigh vacuum technique of secondary ion mass spectrometry (SIMS) is the most sensitive of all the commonly employed surface analytical techniques. There are a number of variants of the technique; for example, static SIMS is used to examine submonolayer elemental analysis, dynamic SIMS is used to obtain compositional information as a function of depth below the surface, and imaging SIMS is used for spatially resolved elemental analysis. Specimens commonly examined by SIMS are ~2.5 cm in diameter and 1 cm thick. When ceramic materials are examined, sample charging is prevented by flooding the surface of the sample with an electron beam. Dynamic SIMS is of great interest and has been used to study changes in elemental composition from weathered or corroded surfaces of samples into the bulk matrix.

## Compositional Analysis of the Bulk Using Powdered Samples or Solutions

### X-Ray Diffraction

X-ray diffraction (XRD) is frequently used to study the crystalline phases present in powdered ceramic samples, or to examine their weathering products, efflorescence samples on the surface of deteriorated ceramics, and metallic corrosion products. The characteristic patterns produced are identified by comparison with those held in a database of known inorganic and organic phases. Although a wide range of diffractometers are available in museum conservation laboratories from the Debye-Scherrer camera (for single crystal analysis) to diffractometers that allow analyses of whole objects, most instruments used in archaeological or conservation labs are designed to analyze small samples of powders (destructive analysis).

### Atomic Absorption Spectrometry

Atomic absorption spectrometry (AAS) (in combination with XRF) has been used to examine a variety of metal alloys including European Medieval brass objects, glass specimens (Egyptian, Renaissance Venetian, and medieval Scottish cathedral glass) and to determine the composition of corrosion crusts on metal surfaces. It is also used to track changes in the composition of specimens after accelerated aging experiments. The specimens need to be drilled into the bulk to produce sample weights between 0.015 and 0.5 g. Samples are digested to produce solutions that are analyzed to determine the concentration of metal ions in solution. The technique offers excellent detection limits permitting trace element analysis ( $\sim 0.1$ – $1$  ng ml<sup>-1</sup> for a furnace and  $10$  ng ml<sup>-1</sup>– $1$   $\mu$ g ml<sup>-1</sup> for a flame atomizer). However, a disadvantage of the system is that elements are detected sequentially as the light source used is changed for each element. Thus, it is not suitable for screening tests, and some prior knowledge of the elements expected is desirable.

### Inductively Coupled Plasma-Atomic Emission Spectrometry

The sample being analyzed is introduced into the plasma as a fine droplet aerosol. Light from the different elements is separated into different wavelengths by means of a grating and is captured by light-sensitive detectors. This permits simultaneous analysis of up to 40 elements and inductively coupled plasma-atomic emission spectrometry (ICP-AES) is consequently a multielement technique. In terms of sensitivity, ICP-AES is generally comparable to flame atomic absorption, for digestion of sample sizes between 0.1 and 0.5 g. The disadvantage is similar to AAS in that it is a destructive technique; however, it has been extensively used for the determination of deterioration products removed from the surface of specimens, and to assess the effect of accelerated aging experiments. To reduce detection limits further, and for the analysis of complex unknowns ICP-mass spectrometry (MS) is used. Laser ablation ICP-MS has been used for the direct sampling of metals. The sample preparation required is reduced significantly; however, the penetration depth is only 10  $\mu$ m, so care has to be taken not to misinterpret the results.

### Lead Isotope Ratio Analysis

The ratios of the four lead isotopes ( $\text{Pb}^{204}$ ,  $\text{Pb}^{206}$ ,  $\text{Pb}^{207}$ , and  $\text{Pb}^{208}$ ) in a lead ore specimen will depend upon the geological age of deposition of the ore. Thus, the lead isotope ratios are used to source the deposit used to produce archaeological objects containing lead. Destructive sampling of the specimen is

necessary, although specimen sizes can be as small as 1 mm<sup>3</sup>. The sample preparation is lengthy and involves the initial dissolution of samples in hydrofluoric and perchloric acids and dissolution of residual solids in dilute nitric acid. The lead is then precipitated from the nitric acid as lead sulfide, which is evaporated onto a filament coated with saturated boric acid, and subsequently heated to produce a fused boric oxide/lead sulfide bead. The concentration of the lead isotopes in the specimen are then determined using ICP-MS. The technique has been applied to study lead alloys, and ancient glass materials with high lead oxide contents such as red and yellow opaque glasses.

### Ion Chromatography

Water-soluble salts in stone, ceramics, and pottery are commonly assessed using ion chromatography (IC). The technique has also been used extensively to determine the composition of efflorescence salts on the surface of deteriorated ceramics and glass specimens, and to investigate the change in composition of specimens after accelerated aging experiments. Sample quantities range from 1 mg to a few grams, depending on the concentration of soluble ions in the sample. Detection limits are in the low parts per million range for most anions and cations (better detection limits can be achieved if ultraclean water sources are used to prepare the eluent, standards, and samples). Thus, the technique is commonly used to study differences in trace element compositions.

### Introduction

Examination, conservation, and restoration of paintings (easel painting, wall paintings, and murals) have been undertaken almost as long as painting has been practiced. Since early articles reported the result of analyses of artists' materials in the late eighteenth century, the subject has emerged as a serious scientific area of research. It is perhaps fair to comment that the expansion of knowledge of artists' materials correlates with the development of improved analytical instrumentation capable of determining the composition of materials on a microscopic level with accuracy and precision. As the level of sophistication of instruments, and data manipulation techniques, increase so does our interpretation of analytical data providing a greater understanding of the materials used, their stabilities, and past technologies used to produce artworks. The main emphasis of this article is to discuss, briefly, many of the analytical instruments involved in the conservation of art works such as easel and wall paintings, murals, and illustrated manuscripts. This short article is not intended to be an exhaustive list of techniques used, but to indicate the great importance of analytical science in this area of research. Thus, in addition to the introductory sections, the article contains five short sections dedicated to (1) microchemical tests, (2) optical investigations, (3) the identification

of traditional and synthetic pigments, (4) identification of resins, waxes, and glues, and (5) the use of lasers in modern day studies of art. Further reading is recommended to explore the many detailed case studies that employ specific analytical techniques.

### Why Do We Study Works of Art?

Many studies implemented focus on identification of pigments and binding media used in an artwork, or they study the artwork as a whole. It is often argued that the most important reason for identification of pigments is for the purpose of restoration. Where possible, original pigments (or a combination of safer alternative pigments) should be used to in-paint damaged areas of a painting. However, the types of pigments used in paintings also provide information to:

1. establish its origin, thus aiding provenance studies;
2. detect forgeries (for example, the year in which a synthetic pigment was synthesized can act as a marker, or the pigments identified are assessed to see whether or not they would have been used on a work of art by a particular artist at a certain period of time);
3. identify which pigments should be used in conservation of a painting;
4. assess the stability of the painting should it experience increased exposure to light, heat, relative humidity, or pollution (for example, inorganic

pigments are generally more photostable and can be exposed to a higher light lux than organic pigments, which are prone to photochemical degradation);

5. understand the development of artistic styles.

Organic materials used as painting media (such as drying oils, waxes, gums, resins, egg, milk, and animal glues) are also subject to analytical scrutiny. Before the development of synthetic pigments artists' techniques differed more in the binding media than in the pigments used, thus examination of binding media has considerable importance for the study of paintings and their associated techniques. Identification of the exact organic component used is difficult even when the artwork is in a pristine condition. The analysis is made even more difficult when the materials examined have undergone some form of deterioration over time. In addition, artists frequently experimented with different, less common, formulations and additives. For example, in the late eighteenth and early nineteenth centuries, terpenoids (balsams, resins, turpentine), prepolymerized plant oils, and waxes were commonly added to modify oil paint. Many of these oil paintings are now showing evidence of failure such as shrinkage, darkening, and flaking. Identification of the presence of additives that may have exacerbated the deterioration in small paint samples is a difficult analytical task. For these reasons identification of binding media is one of the most difficult questions addressed by analytical scientists working in this area of research.

Preventive conservation of the full artwork is becoming increasingly more important in recent years. Unfortunately, damage to artwork is common and forms of deterioration include structural damage such as detachment and loss of paint layers, distortions in the canvas, and structural decay of the painting's support. Chemical changes can cause discoloration of paint and varnish layers, and changes in the chemical composition of the support. The changes can occur naturally over time or they can be invoked or exacerbated by changing environmental factors such as temperature, relative humidity, light, and pollution. The full painting is studied to determine whether or not the artwork will be stable under certain environmental conditions imposed during storage or display. Often, test panels are prepared, dried under normal and accelerated aging conditions, and the materials are studied before and after aging to help predict the future stability of materials, or to select appropriate conditions to protect the artwork for years to come.

## **What Are the Analytical Considerations?**

There are different categories of examination that must be considered in any conservation or restoration treatment. First, information is gathered about the history surrounding the artwork from the materials and techniques used in its construction, to previous conservation or restoration treatments. The analytical procedure is initiated at the next step, which involves the technical examination of the artwork. One of the main considerations is in the selection of appropriate instrumentation. The choice of instruments used in the study will be based upon consideration of factors such as the ability to perform nondestructive analysis, the instrument's detection limits, the sensitivity of the response, sampling requirements (including the preparations involved), availability of instrumentation, and cost. To date, a large range of equipment has been used to examine works of art and often more than one technique is used to solve a particular problem. Knowledge of the limitations of each instrument used is imperative as, for example, the analytical scientist must be able to distinguish between the absence of an expected analyte due to loss or deterioration rather than detection limitations. It is equally important to realize that the selection criteria must also consider the form of analytical data required to answer the carefully derived, relevant problem.

Sampling is a controversial topic when working with valuable works of art, or where extremely small amounts of a sample are taken from a work of art. Nondestructive methods of analyses are usually the goal of the restorer or conservator. However, even when artworks can be examined noninvasively there are handling, storage, transport, and security issues to be considered if the artwork needs to be removed from its location and taken to a laboratory for analysis. For these reasons, where possible, samples are removed *in situ* from artworks to carry out the identification. In general, sampling is often permitted for paintings (microscopic samples are removed from damaged areas); however, it is almost never permitted for manuscripts owing to their fragility. Finally, it is important to ensure that the microscopic sample taken from the artwork is representative of the materials used in the painting, and that the samples are retained with the conservation documentation.

## **Microchemical Tests**

In conservation laboratories microchemical tests are used to identify metal ions in pigments. Before the test is applied it is necessary to remove insoluble

organic resins that have encapsulated the pigment by wet-ashing the sample with hot perchloric acid. If the residue is not water soluble at this stage a drop of aqua regia is added and the wet-ash stage is repeated. Metal ions present in the digested samples can then be determined. For example, lead ions precipitate as thin yellow hexagonal plates when a very dilute drop of aqueous potassium iodide is mixed with a very dilute solution containing lead ions. For those metal-containing pigments that do not dissolve in either perchloric acid or aqua regia (for example, chromium oxide, cobalt blue, quartz, smalt, titanium white), insolubility is in itself an indication of the pigment used, although further tests are required for conclusive identification. A wide range of screening tests are also available for the study of oil or proteinaceous binding material in paint cross-sections.

### Optical Examination of Pigments

Because of its low cost and widespread availability, polarized light microscopy (PLM) is one of the most common and useful instrumental aids for the identification of pigments from detached paint samples, their cross-sections, or dispersions. A number of characteristics are used in combination to identify pigments including shape, size, transparency, association, homogeneity, color, pleochroism, refractive index, birefringence, sign of elongation, and extinction. The technique is particularly useful for identifying amorphous substances such as smalt, cobalt blue, Van Dyke brown, and charcoal, and to differentiate between pigments that have the same composition but differ in source or processing, e.g., whiting as chalk, limestone, or precipitated calcium carbonate. It should be emphasized, however, that correct answers will only be obtained after the analytical scientist masters the skill of PLM.

### The Use of Modern Analytical Equipment to Identify Traditional and Synthetic Pigments

A wide range of analytical techniques is necessary to provide an unambiguous identification of pigments in a sample. Elemental techniques are often used, such as scanning electron microscopy (SEM) with energy-dispersive spectroscopy (EDS), X-ray fluorescence (XRF) spectrometry, scanning electron microprobe analysis (EPMA), X-ray photoelectron spectroscopy (XPS), particle-induced X-ray emission (PIXE), neutron activation analysis (NAA), atomic absorption spectrometry (AAS), inductively coupled

plasma-atomic emission spectrometry (ICP-AES), and inductively coupled plasma-mass spectrometry (ICP-MS). Further information on the use of these techniques in archaeological or conservation research is given elsewhere. Often, more than one technique is required to confirm the range of pigments contained in any one sample, for example, where inorganic pigments can be dissolved they are examined using AAS, ICP-AES, or ICP-MS. Solid samples are more commonly examined by techniques such as XRF, PIXE, or SEM-EDS. Although less common, NAA has been used to examine underlying paint layers of a sample. Immediately after irradiation a series of photographic films are placed in contact with the surface of a painting. Upon development the films show the distribution of pigments that contain radioactive materials at the time of exposure. Different autoradiographs are obtained depending on the decay times of the radioactive elements in the sample. This form of analysis is used to study elements in various pigments used in the seventeenth century such as Mn, Cu, Na, As, P, Hg, Co.

Other techniques are used to identify pigments based on their molecular fragments. These techniques include UV-visible reflectance spectroscopy, infrared (IR) spectroscopy, mass spectrometry, and X-ray diffraction (XRD). Some thermal methods exploit differences in physical characteristics that are sensitive to the bulk properties of a paint sample. Differential scanning calorimetry (DSC) and thermal gravimetric analysis (TGA) are often used. Finally, separation techniques such as liquid chromatography (LC) have been used to identify a wide range of dyes.

Overall, it is important that the chosen techniques produce informative data from microscopic samples, even a single grain of pigment if necessary, and that signals from other materials do not interfere during the analysis. The choice of which technique to use depends on whether or not it can be applied *in situ*, its specificity, sensitivity, spatial resolution, and immunity to interference. For example, IR is highly specific and particularly useful for organic pigments, but it is prone to interference from binders and supports. SEM-EDS provides good spatial resolution but is not normally applied *in situ*, or without coating the pigment with a good electrical conductor. XRF is not as useful for organic pigments as they contain light elements. Noncrystalline pigments such as van dyke brown, bitumen, lamp black, and smalt are amorphous and cannot be analyzed by XRD. The experiences and knowledge of both the analytical and conservation scientists are therefore important when deciding on the most appropriate analytical technique to employ.

## Separation Techniques for the Analysis of Organic Binding Media

Materials used as ancient painting media are complex mixtures of organic compounds including resins, oils, waxes, animal glues, egg, and milk employed alone or in combination. The molecular structures of many of these individual components invariably become even more complex with age, as a result of oxidative changes, the joining of molecular units by polymerization, and the cross-linking and molecular scission of some components. As the identification of binding media in paintings is one of the most difficult questions addressed by analytical scientists, the procedures used to elucidate the composition of such mixtures must include separation steps. Thin-layer chromatography is used to identify oils, resins, and waxes using silica stationary phases. For oils (such as linseed, walnut, and poppy seed) and egg yolk, a liquid phase containing hexane and diethyl ether is used to separate the analytes in the sample and the spots are developed using iodine vapor. For the study of resins such as shellac, copal, and seedlac, chloroform is used as the liquid phase and spots are developed with 20% antimony pentachloride in chloroform. A 9:2:1 mixture of chloroform–diethylether–formic acid solution is used to resolve waxes such as beeswax and paraffin wax after development of the plate using 20% antimony pentachloride in chloroform.

Analysis of oils and proteinaceous binding materials are often performed by gas chromatography (GC) with flame ionization detection. Before analysis the oils are first transformed into their corresponding free fatty acids, and the proteins into their amino acids. The hydrolyzed samples are then derivatized to produce volatile products before they are injected into the GC instrument. With its lower detection limits, higher sensitivity, and ability to identify unknowns, GC–mass spectrometry (MS) is the most widely accepted technique for the analysis of traditional binding media in oil paintings. It is also used for the determination of modern synthetic binders that contain high molecular weight polymeric materials such as polyvinyl acetate; thermally labile fragments are introduced to the system via a pyrolysis analyzer. Considerable success has also been achieved for the analysis of proteinaceous media (collagen, animal, and fish glues) by LC after hydrolysis of the samples and derivatization with phenyl isothiocyanate. For example, using this method high quantities of hydroxyproline are used to indicate the presence of collagen, animal or fish glues, whereas trace quantities of this analyte indicate the presence of egg white or egg yolk.

To assess the stability of, and the effect of changing environmental factors on, binding media reconstructed paint formulations are often subjected to accelerated aging tests. Chemical and physical changes in the components are studied to help determine how, for example, the mechanisms of oxidation and cross-linking of an oil paint are affected by increased temperature and humidity over time. Changes in the molecular weight distribution of additives have been assessed using size-exclusion chromatography with refractive index and ultraviolet detection. To assess subtle changes in composition it is common to use more sophisticated (often coupled) techniques. For example, direct temperature resolved mass spectrometry and electrospray Fourier transform MS have been used to examine chemical changes in the triglyceride composition of oils as a result of oxygenation and cross-linking. Thermally assisted hydrolysis and methylation pyrolysis GC–MS has been successfully used for the analysis of traditional oils and natural resins, a technique that is not only very sensitive but also involves minimal sample preparation.

## Pigment and Media Analysis Using Laser-Based Technologies

Laser-based analytical techniques – such as laser induced fluorescence (LIF), laser induced breakdown spectroscopy (LIBS), and Raman spectroscopy – are also used for the identification of pigments, binding media and varnishes. In all techniques a low-intensity laser is used to excite an extremely small area of a paint sample. The signals generated provide information that can be directly related to reference samples of the molecular structure of pigments, inorganic and organic binding media.

Using LIF both inorganic and organic fluorescent species can be identified by interpretation of the broadband fluorescence spectra they produce. The spectrum obtained is characteristic of the species under examination. However, one limitation of LIF is the analysis of pigments that have low fluorescence quantum yields, they are almost impossible to detect especially in the presence of fluorescent impurities.

LIBS is strongly recommended for elemental analysis of cross-sections as the majority of encrustations and overpaint layers, as well as pigments, contain metals. One of the main advantages of this technique is that extremely small samples can be examined (0.1 nm) compared to traditional methods of analysis by Fourier transform infrared where a few milligrams are needed, even with a diamond cell instrument. No further sample preparation is required as

the sample is ablated creating a microscopic crater only several tenths of a microgram in diameter and 0.1  $\mu\text{m}$  in depth. Thus, the technique is normally attributed as noninvasive. LIBS offers exceptional selectivity as a result of sharp line emission spectra. The individual frequencies and relative proportions of the atomic emission lines provide characteristic fingerprints for most elements providing unambiguous identification. Although there may be interference from background emission from the organic matrix in which the pigment is dispersed.

Raman microscopy has become a powerful tool in the investigation of pigments and organic media in paintings. The high spatial resolution of the microscope makes it possible to examine individual grains of pigment in a sample. Fluorescence from binders can be minimized using an aperture at the secondary focus of the scattered radiation. If the pigment itself fluoresces the excitation wavelength of the laser can be altered to a lower frequency to significantly reduce the fluorescence. On excitation of the sample the inelastic, Raman, scattering gives rise to many bands, which are known collectively as a Raman spectrum. The spectra are highly specific in wavenumber, intensity, and bandwidth to the sample, and thus provide a unique fingerprint of the sample. In a typical setup a microscope is coupled to a spectrometer with a sensitive diode array or CCD detector. There are some limitations; for example, certain organic pigments are photosensitive, or fail to yield a Raman spectrum owing to their small particle size and/or high degree of dilution (such as a lake). The nondestructive nature of Raman microscopy, together with the possibility of *in situ*, highly specific analysis, makes it especially useful for analysis of illustrated manuscripts where sampling is not normally permitted. Moreover, illustrators, even in medieval times, preferred to use inorganic pigments since these colors were known to be less fugitive.

## Introduction

This article concerns the application of analytical biochemical techniques to preserved organic remains

**Table 1** Summary of the main methods used in the identification and characterization of a selection of ancient organic materials

<i>Material</i>	<i>Methods used</i>	<i>Purpose</i>
Bone and teeth	aDNA	Identification of species of origin, phylogenetic analysis, sex determination, pathogen identification
Bone and teeth	Stable isotope analysis	Determining diet and place of origin
Parchment	aDNA	Identification of species of origin
Parchment	Immunochemistry	Identification of species of origin of proteins
Pottery residues	GC/MS, GC–IR–MS, Pyr–GC–MS	Identification of lipid origin, especially plant and animal fats
Pottery residues	Immunochemistry	Identification of species of origin of proteins
Stone tool residues	Immunochemistry	Identification of species of origin of proteins
Resins	GC/MS, GC–C–IR–MS, Pyr–GC–MS	Identification of plant of origin
Soil lipids	GC/MS, GC–C–IR–MS, Pyr–GC–MS	Identification of lipid origin, especially manure

recovered from archaeological or historical contexts. The preserved material is often greatly altered compared to its modern counterparts; therefore, modified extraction procedures are required, as are a number of tests to determine the degree of preservation. This research area has grown rapidly in recent years, driven by advances in technology, especially in the ability to measure very small samples, which is necessary as many of these methods are destructive, and the material of interest is often rare. The goal of research in this area is to both correctly identify and isolate biomolecules of interest, and then derive information of archaeological or historical interest from them (Table 1). Because of this focus, this area of archaeological science research is often termed ‘biomolecular archaeology’.

## Ancient DNA (aDNA)

DNA has been successfully recovered from a range of ancient organic materials, including tissue, bone, and teeth. The methods used are derived from standard biomolecular techniques of DNA extraction, amplification, cloning, and sequencing, but are modified to account for the degraded state of the DNA. The goal of this area of research is twofold; to first recover intact DNA, and to then sequence the DNA. The may be done to simply determine biological species, or it can be used to determine the phylogenetic affinities of ancient samples.

### aDNA Application: Human Bone and Teeth

aDNA extracted from human bone and teeth can potentially be used to determine the sex of an individual, provide phylogenetic information, indicate familial relationships, and identify the presence of disease pathogens. However, much of this potential is yet to be realized as this area has been greatly hindered by the problem of contamination by modern human and pathogen DNA. aDNA is often present (if at all) in significantly smaller quantities

than in modern bone and teeth, and is often fragmentary. As there is so little aDNA the sequences need to be amplified using polymerase chain reaction (PCR), which is where the errors can occur. PCR is designed for modern DNA, and therefore can better amplify modern intact molecules than fragmentary ancient ones. Contamination of samples can occur in both the field and the museum, as modern DNA can be introduced to the bone or tooth through handling the samples, or during cleaning of the samples. Contamination in laboratories is also a problem, although most modern laboratories have adequate procedures in place to limit this.

Researchers have endeavored to extract and amplify mitochondrial DNA (mtDNA) as well as sections of nuclear DNA from ancient samples. mtDNA is inherited maternally, so the sequence can show maternal lineage, and modern (living) human mtDNA sequences have been used to attempt to reconstruct the genetic history of Europe, focusing on whether extant peoples are descendents of Palaeolithic or Neolithic peoples, or even later migrations. This area of research is problematic even with modern humans, and with the problems of contamination it is nearly impossible with ancient samples. Recent research has shown, for example, that damage to the DNA can cause changes in the sequences that mimic other mtDNA sequences, so for example, a ‘European’ mtDNA sequence could be altered upon burial to resemble a ‘Near Eastern’ sequence. The great success of this research has been the successful extraction and sequencing of a number of Neanderthal mtDNA sequences, which showed that Neanderthals had significantly different mtDNA sequences than all of the living humans currently sequenced, and were therefore our ‘cousins’ and not direct ancestors.

Nuclear DNA sequences could provide significant information on phylogeny, familial relationships, and genetic disorders, but aDNA is often so fragmentary that it is difficult to sequence. Also, researchers are currently working on understanding the modern

human genome, so we cannot hope to understand the functions of past gene sequences until we understand modern ones. Some work has been undertaken on trying to use DNA to sex individuals, looking for the presence of the Y chromosome to indicate a male sequence. Again, contamination is a very significant problem here and this method is controversial.

A third area of aDNA research is the attempts to identify and amplify pathogen DNA from bone. Again, this method is in its early stages and almost all of the results published so far have been challenged. A major problem with this analysis is that the pathogen DNA is likely to be present in extremely small concentrations, if it has survived at all. A number of researchers have attempted to identify the pathogen that causes tuberculosis (*Mycobacterium tuberculosis*) with some success. However, it is important to note that the presence of this pathogen does not mean that the person actually had the disease, but could simply have been a carrier.

Due to contamination problems, most aDNA researchers will not use curated human skeletal material for analysis, but will only work on currently or recently excavated material. Preferably, bones will be excavated by people whose DNA sequences are known, either someone from the DNA laboratory or by a designated excavator.

#### **aDNA Application: Animal Bone and Teeth**

Following the same procedures outlined above for human bone and teeth, it is possible to identify the species of unidentified bone fragments, as well as produce phylogenetic information on certain species. For example, the sequences of living and ancient cattle samples from Europe and the Near East have been sequenced to determine when and where cattle were domesticated. If these analyses are undertaken in laboratories that have not analyzed modern animal samples, then there is much less concern about contamination. For this reason aDNA analysis of faunal samples has been among the most successful applications of this method.

#### **aDNA Application: Species Identification of Organics**

By extracting and then amplifying intact DNA from organic materials it is possible to determine the species of origin of that organic material. This is done using a range of species-specific PCR primers. These primers, as well as methods to characterize the DNA extract, have to be modified to account for the very fragmentary nature of the aDNA. With these methods, and providing that the DNA is still reasonably

intact, it is possible to identify the species used, for example, in producing parchment. Researchers have also been able to extract aDNA from animal coprolites, providing information on the range of plant and animal species the organism consumed.

#### **Stable Isotope Analysis**

Stable isotope analysis (SIA) method uses the stable isotope ratios of various elements as biological tracers. Human and animal body tissues are composed of elements that are ingested through food or water. The isotope ratios of stable isotopes of some of these elements (e.g., C, N, S, O, H, Sr, and Pb) from food and water are preserved in bone and teeth. Therefore, we can measure the isotope ratios of those elements in bone and teeth and then, by comparing those values to known isotope values of possible foods and water sources it is possible to determine aspects of past diets (palaeodiet) as well as the location where that human or animal consumed the food and water (migration).

Extraction procedures vary depending on the element of interest, and focus on purifying a specific component of bone and teeth. As with any study of preserved organics, contamination and degradation of the materials of interest is a problem. Therefore, extraction procedures are designed to both extract as much intact molecules as possible, and then characterize that component to determine the extent of degradation and contamination.

Measurements of the stable isotope ratios are conducted using mass spectrometers. For the light stable isotopes of carbon, nitrogen, oxygen, sulfur, and hydrogen it is possible to use continuous flow isotope ratio mass spectrometry. Here, the sample is combusted (C, N, S) in the presence of oxygen, or pyrolyzed (O, H) using glassy carbon, in an elemental analyzer in a stream of helium. The resultant gases are then passed through an isotope ratio mass spectrometer, which measures the relative amounts of the two stable isotopes of interest. For the heavier isotopes of strontium and lead it is necessary to purify the sample in a clean laboratory, as the concentrations in bone and teeth are on the order of parts per million or parts per billion, and then the solution is analyzed using inductively couple plasma-mass spectrometry (ICP-MS). It is also possible to use a laser, coupled to an ICP-mass spectrometer, to ablate bone and tooth samples, which reduces the needs for extensive sample preparation and allows targeted sampling of very small areas of bone and teeth.

By convention, light stable isotope values are reported using the delta notation, in parts per thousand. For example, the isotope ratio of the stable

isotopes of carbon,  $^{13}\text{C}$  and  $^{12}\text{C}$ , are reported as  $\delta^{13}\text{C}$  values according to the formula:

$$\delta^{13}\text{C} = (((^{13}\text{C}/^{12}\text{C}_{\text{sample}})/(^{13}\text{C}/^{12}\text{C}_{\text{standard}})) - 1) \cdot 1000$$

### SIA Application: Bone and Tooth Protein to Reconstruct Palaeodiet

Stable isotope analyses as used in modern and archaeological dietary studies endeavors to determine the dietary sources of carbon and nitrogen found in body tissues by measuring the ratios of the two stable carbon isotopes,  $^{13}\text{C}$  and  $^{12}\text{C}$ , and the ratios of the two stable nitrogen isotopes,  $^{15}\text{N}$  and  $^{14}\text{N}$ , in foods as well as in the body tissues of interest. The ratios of these isotopes are compared to known standards and are presented as  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  values. Most of this research focuses on isotope measurements of the best preserved organic component of bone, the protein collagen (which comprises  $\sim 20\%$  of modern bone by weight). Collagen carbon and nitrogen is largely derived from dietary protein and likely reflects dietary inputs from approximately the last 10 years of life. Carbon isotope values indicate whether dietary protein came from marine or terrestrial sources, and it can also distinguish between  $\text{C}_3$  and  $\text{C}_4$  photosynthetic-pathway plants. Mammal collagen  $\delta^{15}\text{N}$  values indicate the trophic level of an organism in a food web, as there is an increase in the  $\delta^{15}\text{N}$  value of  $\sim 2\text{--}4\%$  each step up the food chain. Collagen  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  values are specific to regions and ecosystems, and can also vary through time, related possibly to

climatic effects. Therefore, it is important to take the ecosystem approach to isotope analyses and measure the  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  values of fauna associated temporally, as well as spatially, with the humans of interest (Figure 1).

Additionally, studies of infant and juvenile bone and teeth  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  values can tell us about the age of weaning in past populations, as infants that are breastfeeding have  $\delta^{15}\text{N}$  values that are higher than their mothers, which then drop to lower values when the child is weaned onto solid food.

Sampling protocols for carbon and nitrogen isotope analysis are fairly simple, as is the extraction procedure. This method requires the extraction of the protein collagen from bone, and then the further purification of this collagen for isotope analysis. SIA often requires only a few hundred milligrams of bone, less if the bone is well preserved.

### SIA Application: Bone and Tooth Mineral to Study Migration

Bone mineral and dental enamel oxygen isotope values reflect the oxygen isotope values of the water that a mammal consumes. If that mammal is migratory between climatic zones that have very different oxygen isotope ratios then the different values may be recorded in the bone or enamel. Therefore, oxygen isotopes have the potential to identify migrating species or humans. There are many exciting possibilities with oxygen isotopes of bone and enamel, but there are also serious concerns over contamination

**Figure 1** Typical carbon and nitrogen stable isotope ratios of collagen extracted from various species. In this example the terrestrial animals consume only  $\text{C}_3$  plants (herbivores and omnivores) or animals that consume only  $\text{C}_3$  plants (carnivores and omnivores). The marine organisms are distinguished from the terrestrial organisms through the  $\delta^{13}\text{C}$  value, which is less depleted in  $^{13}\text{C}$ . The  $\delta^{15}\text{N}$  value indicates the trophic level of an organism in the food web.

of bone and enamel by soil and groundwater oxygen. Generally, enamel has been shown to be much more immune to contamination than bone.

The measurements of the concentrations of various trace elements in bone and teeth has been used to determine past diets, but this area has largely been discredited in recent years, due to probably insurmountable problems with diagenesis and the uptake of new elements from the soil into the bone. However, promising advances are being made using the isotopes of some of these elements, like lead and strontium, to determine geographical place of origin of individuals. Currently, bone is not an appropriate material for this analysis, due to contamination problems, but tooth enamel is more resistant to diagenetic changes, and in some cases, can be used for this analysis. Usually, the whole tooth is used for these analyses, as trace element concentrations across the tooth need to be measured to test whether there has been soil contamination.

## Organic Residue Analysis

Organic residue analysis (ORA) focuses on the characterization, primarily for identification purposes, of ancient organic residues that have been preserved, often because of an association with an inorganic material. As with the other areas discussed here, researchers in ORA need to modify their analytical techniques for application to degraded and damaged surviving organics. There has been much erroneous identification published in the literature stemming from an inadequate appreciation of the degraded state of preserved organic molecules, and not recognizing that modern techniques need to be modified for ancient samples.

This area uses a variety of analytical methods. To identify and characterize lipids the main analytical technique employed is gas chromatography (GC), often in association with mass spectrometry (GC-MS). Newer advancements include the use of pyrolysis-GC-MS and the measurement of the stable isotope values of individual compounds in GC-C-IR-MS. To identify proteins a range of immunochemical identification techniques are used, including enzyme-linked immunosorbent assay and radioimmunoassay.

### ORA Application: Lipid Residues in Pottery

The most successful use of these identification methods is in the identification of preserved organics in pottery. It is likely that these residues are incorporated into the pottery through cooking, and survive as they are associated with the mineral structure of the pot, although the mechanisms are poorly understood.

GC-MS analysis of pottery can identify the presence of lipids derived from plant or animal sources, using the presence and ratios of various fatty acids. It is not possible to further define the source of the fats using reference values for these ratios from modern fats, as archaeological samples are greatly degraded, which changes the relative amounts of fatty acids. However, further identification of the source of the lipid fatty acids is possible through the use of GC-C-IR-MS. This significant advancement in the field measures the  $\delta^{13}\text{C}$  values of fatty acids of interest, allowing the identification of ruminant versus non-ruminant fats, as well as lipids derived from milk. A great success of this method has been the identification of the earliest use of milk in Britain.

Other compounds in pottery that can be identified using GC-MS are beeswax, identified by the distribution of *n*-alkanes and long-chain palmitic wax esters. Plant oils can also be possibly identified, and identification is often enhanced through the use of GC-C-IR-MS.

Sample preparation is relatively simple. A subsample of the potsherd is ground to powder and the lipids are then removed with the use of solvents such as chloroform and methanol. The resulting lipids are then derivatized before being introduced into the GC-MS.

### ORA Application: Protein Residues in Pottery

A significant recent advancement in this field is the application of immunochemical methods to identify proteins preserved in pottery. As with the lipids, the proteins appear to bind to the pottery and are protected and preserved. The proteins are degraded, however, so it is not possible to use antibodies prepared using modern proteins. Instead, new antibodies must be created using degraded proteins, either taken from archaeological samples, or artificially degraded in the laboratory. There is great potential in this method, as it could allow the identification of specific species, whereas GC-MS and GC-C-IR-MS only identify to broad categories. Unfortunately, relatively few pots have preserved proteins.

### ORA Application: Organic Residues on Stone Tools

Residues from plants and animals can be preserved on tools made from stone such as flint or obsidian. However, the processes involved in preserving the organics are also poorly understood, and indeed there has been some debate that stone is incapable of preserving residues, apart from exceptional circumstances. Theoretically, the residues are deposited during the use of the tool, whether that is through the processing of plant or animal foods, or both. Most of the published literature in this area relies on

the use of immunochemistry to identify species of origin of preserved proteins (e.g., blood proteins). This has been confounded by the use of antibodies made from modern materials as well as the use of general antibodies that can give false positive results.

#### ORA Application: Other Residues

It is also possible to characterize other residues found in the archaeological record. Two such residues of interest are natural products such as resins and bitumens and the other are lipids preserved in soils in archaeological sites. Resins from birch bark, pine, and spruce trees have been identified in the archaeological record using GC–MS. These resins have been used to, for example, haft stone tools, and seal and repair pottery. Identification of lipids in soils is a relatively new area, and the use of GC–C–IR–MS has been a major advancement in this area. It is possible to identify the use of manure on fields, which can pinpoint the first farming in a region, as well as help identify farming methods. Additionally, it has been possible to characterize the embalming materials used to preserve Egyptian mummies.

### Introduction

The metalloid arsenic belongs to the same group as the essential elements nitrogen and phosphorus. Like nitrogen and phosphorous, it forms stable oxygen bounds, but in anaerobe environment it prefers sulfur as binding partner. It forms stable penta- and trivalent compounds, whereby inorganic arsenic compounds are often found together with other chalcophilic elements like copper or iron. Organic arsenic compounds, containing one to four arsenic–carbon bounds, are widespread in biological samples. Inorganic compounds of arsenic are widely used in the metallurgy and in the semiconductor industry, organo-arsenic compounds are among others used as pesticides and herbicides.

Arsenic speciation is the analytical activity that leads to the identification and quantification of a

specific form (molecular or complex structure or oxidation state) of arsenic in a given environment (as derived from the IUPAC definition on speciation). It includes sampling, sample preparation, identification, and quantification of the species, under study, without the induction of changes to this species. In the following only such techniques are considered that allow a characterization of functionally defined species. Other techniques defining operational characterized species, like the differentiation of species into soluble and insoluble in a given solvent, are not considered.

The knowledge of the arsenic species present in a given matrix, e.g., water, has a large impact on the health of living beings, since the toxicity of arsenic is strongly depending on its molecular form. Inorganic arsenic species were used as early as 500 BC for their toxic properties and their ascribed beneficial health effects. Arsenic compounds were among others used for the treatment of syphilis. They are still used in some traditional medicines, like Chinese ones, and arsenic oxide has recently been under trial for the treatment of acute promyelocytic leukemia.

Nevertheless, the research into the negative health effects of different arsenic compounds is predominant, especially into the toxicity and carcinogenicity of different arsenic species for humans.

## Arsenic Species

The inorganic arsenious acid ( $\text{As}^{\text{III}}$ ) and arsenic acid ( $\text{As}^{\text{V}}$ ) and their salts are water soluble and present with their high toxic and carcinogenic potential (Table 1) a widespread problem for the water industry trying to provide safe drinking water. Both species are metabolized by most organisms to methylated organo-arsenicals, with often a lower toxic, but not necessarily a lower carcinogenic, potential. Organo-arsenicals exist as do the inorganic species in the penta- and trivalent oxidation state, whereby the pentavalent state is the more stable one in oxidative environments, like dimethylarsinic acid ( $\text{DMA}^{\text{V}}$ ) and methylarsonic acid ( $\text{MA}^{\text{V}}$ ). Recently, the trivalent methylated intermediates ( $\text{MA}^{\text{III}}$ ,  $\text{DMA}^{\text{III}}$ ) enjoyed major attention, since these species show higher toxicity than inorganic precursors. The metabolic pathway of inorganic arsenic to  $\text{DMA}^{\text{V}}$  was first described in 1945 by Challenger. It includes the alternating reduction of pentavalent to trivalent arsenic followed by oxidative methylation. Whereas in humans and most mammals the arsenic metabolism ends with the excretion of the stable pentavalent  $\text{DMA}^{\text{V}}$ , fish and others produce and/or store arsenobetaine, containing four arsenic-carbon bonds, and marine algae among others produce arsenic compounds containing a ribose moiety. Recently, labile arsenic-peptide complexes, tri-(glutamylcysteinylglycyl)trithioarsenite ( $\text{As}^{\text{III}}(\text{GS})_3$ ) and arsenite-phytochelatin(3) ( $\text{As}^{\text{III}}\text{-PC}_3$ ) were identified in mammals and plants, respectively

(Figure 1). These different arsenic species have a wide range of acute toxicity and carcinogenicity toward humans, which makes the determination and quantification of the arsenic species present in, e.g., food or water, mandatory for health and safety reasons.

## Analytical Strategies

Arsenic speciation can be divided into three subtasks each depending on the others:

- sample preparation (collection, preparation, and storage);
- separation of the arsenic species from other molecules (species) present in the sample (by hydride generation (HG), gas chromatography (GC) or liquid chromatography (LC)); and
- detection (element specific and/or molecule specific).

These tasks are described in the following in more detail.

## Sample Preparation

The main focus during sample collection, preparation, and storage has to be the preservation of the arsenic species present in the original or at least to conserve the major functional group information of the species. Most of the pentavalent arsenic species present in biological or environmental samples identified so far, in, for example, urine, are quite stable. Samples containing them can be collected, prepared, and stored without risk of species changes as long as contamination and a change of pH and salinity is avoided and the storage conditions are not reductive.

**Table 1** Selected arsenic species occurring in the environment (E) and biota (B) and their determined acute toxicity for male mice in mg per kg body weight

No. of R	Trivalent species	B	E	LD <sub>50</sub>	Pentavalent species	B	E	LD <sub>50</sub>

**Figure 1** Molecular structures of some selected organoarsenic species occurring with some commonly used abbreviations.

Trivalent arsenic species need a reductive sample environment; this is especially true for methylated species, since these are extremely labile and sensitive to oxygen. A similar problem is presented by arsenic species containing sulfur, whether it is dimethylarsinothioic acid (DMA<sup>V</sup>), where there is a direct arsenic sulfur bond, or arsenic species complexed by sulfur containing amino acids (e.g., As<sup>III</sup>(GS)<sub>3</sub>). Gas samples containing volatile arsenic species (Me<sub>x</sub>AsH<sub>3-x</sub>) can be stored for weeks in the dark, but they oxidize in the presence of ultraviolet (UV) light within hours.

Depending on the intended technique used for separation of the arsenic species most samples need

to be transferred into liquid form without disturbance of the arsenic species. Sample matrices like water or urine do not require much sample preparation except maybe filtration, but other matrices like plant or tissue samples require the use of extraction methods prior to the separation. The extraction method(s) used have to be tested whether they enable the extraction of the arsenic species without changing the oxidation state or in case of complexes binding partners. Many arsenic species, like DMA<sup>V</sup>, arsenobetaine, or arsenosugars are stable enough to survive relatively harsh extraction conditions. For these methanol/water in combination with ultrasonication is an often-used extraction method.

Other arsenic species, like the trivalent methylated intermediates of arsenic metabolism predicted by Challenger, were for many years fairly elusive, because of their instability against oxygen and harsh extraction conditions. The recently identified arsenic–glutathione and arsenite–phytochelatin complexes suffer from the same problem, and can only be stabilized in acidic extracts.

Generally, the sample should be measured after sample collection as quickly as possible with as limited a sample preparation as possible. If sample storage is necessary for some time, subsamples should be stored under different conditions to allow the identification of species transformation during storage (e.g., oxidation, methylation, or demethylation). Lower temperatures,  $-20^{\circ}\text{C}$  to  $4^{\circ}\text{C}$ , are generally more useful than the addition of preservatives and acid, which may have an influence on the speciation.

Over the years a wide range of analytical techniques were employed for the speciation of arsenic, including different separation techniques. Which technique is used depends among others on the question to be answered and the species to be identified.

In addition, it should be mentioned that the highest emphasis until now is on water-soluble arsenic species, which is reflected in the remainder of the article. But it should not be forgotten that lipid-soluble arsenic species (like arsenolipids) exist. However, they need different extraction protocols using mainly lipophilic solvents like methanol/chloroform and different separation techniques.

## Separation of Arsenic Species

The separation technique suited depends on the complexity of the sample matrix and the number of arsenic species present in the sample.

### Hydride Generation Coupled to Gas Chromatography (HG–GC)

HG in its simplest form allows the speciation of inorganic  $\text{As}^{\text{III}}$  and  $\text{As}^{\text{V}}$ . For the speciation of samples containing more than these two hydride-active species, a combination with GC is necessary. Every arsenic species, with the exception of those carrying four carbon bonds, can be transformed into arsines by borohydride. Most of the arsines are volatile and can be separated by GC. Depending on the pH used during hydride formation a distinction between tri- and pentavalent arsenic is in most cases possible. Trivalent arsenic species form hydrides already at pH 7, whereas pentavalent ones are only reactive at pH 1 (Table 2). Measuring the same sample with both pHs

**Table 2** Arsenic species and the arsines formed by treatment with borohydride

Species	Solution pH 1	Solution pH 7 (buffered)
$\text{As}(\text{OH})_3$	$\text{AsH}_3$	$\text{AsH}_3$
$\text{H}_3\text{AsO}_3$	$\text{AsH}_3$	–
$\text{MA}^{\text{III}}$	$\text{MeAsH}_2$	$\text{MeAsH}_2$
$\text{MA}^{\text{V}}$	$\text{MeAsH}_2$	–
$\text{DMA}^{\text{III}}$	$\text{Me}_2\text{AsH}$	$\text{Me}_2\text{AsH}$
$\text{DMA}^{\text{V}}$	$\text{Me}_2\text{AsH}$	–
TMAO	$\text{Me}_3\text{As}$	$\text{Me}_3\text{As}$
$\text{DMAS}^{\text{V}}$	$\text{Me}_2\text{AsH}$	$\text{Me}_2\text{AsH}$

gives therefore the ratio of penta- to trivalent arsenic. It has to be kept in mind that the efficiency of the hydride formation is species dependent and there might be pentavalent arsenic species present in the sample that form hydrides already at pH 7, like  $\text{DMAS}^{\text{V}}$ . HG is routinely used for the determination of inorganic arsenic species and in combination with cryotrapping and GC for the separation of mono-methylated and dimethylated arsenic, since these species are easy to volatilise. Dimethylated arsenosugars, which can as well form volatile arsenic species during HG, have not yet been successfully separated by this technique.

### Gas Chromatography

The volatile hydrides formed during HG with borohydride can be separated on a nonpolar GC column depending on their boiling point. Additionally, gaseous arsines can be trapped cryogenically and separated directly (Figure 2).

### Liquid Chromatography

Over the years especially anion and cation exchange chromatography, ion-pair chromatography, and size exclusion chromatography showed their value in the speciation of arsenic-containing compounds. All these chromatographic methods have the additional advantage that they are well suited for the online combination with most detectors used to detect arsenic species. One example for the separation of the most important arsenic species is shown in Figure 3.

Most arsenic species are either cationic or anionic at a given pH and can therefore be separated by ion chromatography. A two-method approach (anion and cation exchange chromatography) can result in a 2D map of retention times for more than 10 arsenic species (Figure 4) that assists in identification. Using carefully chosen separation conditions the main arsenic species present in biological samples can be separated. More labile arsenic complexes are mostly separated by size exclusion chromatography, which

**Figure 2** CT-GC-ICP-MS chromatogram of an air sample containing large amounts of  $\text{CO}_2$  with and without NaOH cartridges before cryotrapping of 1:  $\text{AsH}_3$ , 2:  $\text{MeAsH}_2$ , 3:  $\text{Me}_2\text{AsH}$ , and 4:  $\text{Me}_3\text{As}$  of a concentration of  $10 \mu\text{g}$  arsenic per  $\text{m}^3$  each.

**Figure 3** Separation of multispecies standard of  $\text{As(III)}$ ,  $\text{DMA(V)}$ ,  $\text{MA(V)}$ , and  $\text{As(V)}$  on a short strong anion exchange column (150 mm PRP X-100, Hamilton,  $30 \text{ mol l}^{-1}$  phosphate buffer adjusted with ammonia to pH 6.0). Concentration of each species 5, 10, 15, and  $30 \mu\text{g}$  arsenic per liter.

is a gentler separation method but suffers from low resolution especially since most arsenic species are present as relatively small molecules. Reverse-phase chromatography can be used successfully for the separation of these labile arsenic complexes (e.g.,  $\text{As}^{\text{III}}(\text{GS})_3$ ) as well. This kind of separation has a much better resolution power than size exclusion chromatography, but is sometimes difficult to combine with elemental detectors like inductively coupled plasma-mass spectrometers, since it uses organic solvents as mobile phase.

Several points need consideration in addition to the ability to separate the arsenic species of interest from other species present in the sample with the chosen chromatographic conditions. One of them is the stability of the species in the eluent and on the

column; another is the recovery rate of the species from the column. A good example for these potential problems is the separation of  $\text{As}^{\text{III}}(\text{GS})_3$ , which is unstable in alkaline conditions and does not elute from a strong anion exchange column except after disintegration to  $\text{As}^{\text{III}}$ .

It is not only necessary to have an inside knowledge of the separation power of the different techniques, more importantly, it is also necessary to know which arsenic species will be hidden by using the separation technique chosen.

Capillary electrophoresis (CE) has been used to separate a number of arsenic species, but up to now problems with matrix effects and the high detection limits do not permit its application to biological and environmental samples.

**Figure 4** Comparison of retention times (min) of standard arsenic species on strong anion and cation exchange columns (Hamilton PRP X-100 (20 mmol l<sup>-1</sup> carbonate pH 8.0) and Sulpelcosil LC-SCX (20 mmol l<sup>-1</sup> pyridine pH 3.0)). Arsenic species: 1: As<sup>III</sup>, 2: As<sup>V</sup>, 3: DMA<sup>V</sup>, 4: DMAS<sup>V</sup>, 5: MA<sup>V</sup>, 6: MAS<sup>V</sup>, 7: MA<sup>III</sup>, 8: AsB, 9: AsC, 10: Me<sub>2</sub>As-sugar-OH, 11: Me<sub>2</sub>As-sugar-PO<sub>4</sub>, 12: Me<sub>2</sub>As-sugar-SO<sub>3</sub>, 13: Me<sub>2</sub>As-sugar-SO<sub>4</sub>, 14: DMAE, 15: TMA<sup>+</sup>.

## Detectors for Arsenic Species

There are two different approaches to detect arsenic species; one is the use of an element-specific detector and the other the use of a molecule-specific detector. Both have their positive and negative points. Using an arsenic-specific detector (ICP-MS) in combination with the chromatography enables the detection and identification of arsenic-containing species by comparing the retention times with those of known standards, but not the identification of the molecules per se which is possible by using a molecule-specific detector, like ES-MS (electrospray mass spectrometer). The use of ICP-MS and ES-MS, the most often used detectors for arsenic speciation, is described in some detail in the following paragraph, with some additional information on the other often used detectors.

### ICP-MS

Most chromatographic techniques can be coupled online to an ICP-MS without any problems. In the harsh ionization conditions of the plasma, molecules disintegrate rapidly and form readily single charged element ions that are separated by their mass charge ratio and detected. The signal intensity of the element is mostly independent of the molecular species prior to ionization, which enables quantification without the need to use identical standard species. Especially in the quantification of arsenic compounds from biological samples, which often contain unknown species, this feature is very useful. ICP-MS is also a quite sensitive technique that often achieves detection limits of a few nanograms or picograms per

sample volume/mass. Using ICP-MS as detector for arsenic speciation with its low detection limits has also some considerable drawbacks. Among these is the complete loss of molecular information, which allows the identification of species only by retention time and comparison with a known standard when coupled with GC or high-performance liquid chromatography (HPLC). This presents the main problem when biological samples are analyzed, since known and well-characterized arsenic species are rarely available.

### ES-MS

ES-MS gives in contrast to the ICP-MS molecular information, mainly the molecular mass of the protonated molecule (in positive mode), and depending on the instrument used it can give information about molecule fragments formed in the high vacuum of the instrument. ES-MS is a so-called soft ionization method during which normally one proton is transferred onto the neutral sample molecule producing, therefore, a single charged cation for small molecules while larger molecules can add multiple protons resulting in multiple charged cations. They are separated by their mass-to-charge ratio ( $m/z$ ) from other molecules. Using either an instrument able to work in the MS/MS mode or repeatedly measuring the same sample with different fragmentor voltages (FVs) does often give useful information about the species. It has to be kept in mind that most biological and environmental sample matrices often contain a number of species that show up at the same  $m/z$  ratio as the arsenic species, therefore making the task of identifying the species in the sample quite difficult to

impossible without additional information. The signal intensity in ES-MS spectra depends on the molecule itself, the exact separation conditions (especially pH and buffer concentration), and on the concentration of co-eluting molecules. Since these factors have an unpredictable influence, quantification by ES-MS in raw sample (extracts) is only possible in standard addition mode when the species is available as pure standard compound.

### Other Detectors

Atomic fluorescence spectrometers (AFS) are sometimes used online for the detection of hydride-forming arsenic species. Nonhydride-forming species, like arsenosugars, can only be determined by AFS after online digestion, although recently a report has revealed that even these arsenosugars may form volatile arsine species. X-ray techniques, like XANES or EXAFS, can be used to determine the electronic environment of the arsenic. These techniques are often applied to determine whether arsenic is bound to sulfur or oxygen atoms. Proton and carbon nuclear magnetic resonance (NMR) can be used for the identification of the organic part of an arsenic species, when the sample is concentrated enough. Samples intended for NMR measurements must be pure; otherwise the assignment of the signals to the hydrogen and carbon atoms in the molecule is not possible. The arsenic nucleus itself is not useful for NMR measurements, since its large quadrupole moment causes extensive line broadening even in highly symmetric molecules like  $\text{AsF}_6^-$ .

Arsenic species might not be separable and detectable due to:

- co-elution with other more abundant arsenic species;
- decomposition of labile compounds during extraction or separation;
- irreversible reaction with the stationary phase; or
- formation of macromolecules that stick to the columns.

## Arsenic Speciation in Environmental and Biological Samples

### Determination of Arsines in Landfill Gas

For example, bacteria living in landfill sites can metabolize the arsenic present in such sites to volatile arsines. For the determination of these highly toxic ultratrace compounds by GC it is necessary to have a series of cleanup steps if GC is coupled to electron impact mass spectrometry (GC-MS) or ICP-MS, since the samples contain dozens of different organic

**Table 3** Estimates atmospheric lifetime of volatile arsenic compounds in moisturized air at a starting concentration of  $10 \mu\text{g m}^{-3}$

	Dark, 20°C	Dark, 50°C	UV, 30°C (5000 lux)
$\text{AsH}_3$	>2000 h	>600 h	150.0 h
$\text{MeAsH}_2$	1440 h	600 h	1.5 h
$\text{Me}_2\text{AsH}$	480 h	84 h	0.1 h
$\text{Me}_3\text{As}$	—	30 h	0.1 h

compounds in high concentrations. Due to the low concentration of volatile arsenic compounds a pre-concentration method is necessary. Cryotrapping (CT) on a packed column filled with nonpolar chromatographic material (SP-2100 on Chromosorb) with subsequent separation of the different species according to their boiling point can be used to pre-concentrate and select the fraction containing arsenic species. The fraction is collected and injected again onto a second column. This time the column has a higher separation power and a different polarity, so that an unequivocal identification of the volatile metal species can be made by fragmentation patterns of the eluting molecules using GS-MS. Once the structures are fully established using this method, capillary-GC can be coupled directly to ICP-MS without the use of a molecule-specific detector. ICP-MS is much more sensitive for the different metal species, which makes the cleanup steps redundant. **Figure 2** illustrates the sensitivity of the CT-GC-ICP-MS with detection limits at the subpicogram level. Using a NaOH cartridge,  $\text{CO}_2$  can be absorbed before the gas sample is cryotrapped (**Figure 2**). This technique was routinely used for the stability testing of volatile arsenic species in moisturized air at room temperature and at 50°C in the dark and under intense UV radiation. Concentrations of  $\sim 10 \mu\text{g}$  arsenic per  $\text{m}^3$  are a realistic concentration in order to find out whether volatile species have a high enough atmospheric lifetime to diffuse in the vicinity of point sources such as landfill sites. The stability of arsines depends on the methylation grade, temperature, and more significantly UV radiation in the environment (**Table 3**).

### Arsenic Metabolites of Inorganic Arsenic in Mammals

Ingested arsenate and arsenite are taken up in the intestine and transported by the blood into the liver, which is the major site of arsenic metabolism before excretion by urine.

The main excreted forms are dimethylarsinic acid ( $\text{DMA}^{\text{V}}$ ) and methylarsonic acid ( $\text{MA}^{\text{V}}$ ); in addition, several minor arsenic compounds can be found in urine depending on the amount of ingested arsenic

and duration of exposure. LC coupled to ICP-MS is the most sensitive way to study arsenic species in urine with detection limits of less than 1 ng As per ml. Anion exchange and cation exchange chromatography are the main separation techniques. Since ICP-MS is an element-specific detector the availability of pure, precisely characterized standard compounds for identification is essential as the careful check, even if a chromatographic signal contains more than one arsenic compound. Using only anion exchange chromatography can lead to misidentification of cationic species such as arsenobetaine as arsenite, since both compounds are very difficult to separate on such a column (Figure 4). For the identification of co-eluting cationic species the use of cation exchange chromatography is essential. Nevertheless, misidentification can be anticipated using only ICP-MS as detector. Unknown species like dimethylarsenothioyl acetic acid, recently found in urine, can only be identified using elemental and molecular detectors and the characteristic fragmentation pattern of the species (Figure 5).

### Arsenic in Biota

Plants have developed a whole range of ways to deal with high arsenic concentrations in their environment; some even actively accumulate arsenic to extremely high levels. To avoid toxicity they reduce either the uptake of arsenic (in soil/water mostly present as arsenate) by reducing the transporters for phosphate that are used for the uptake of arsenate. Another way to deal with the high toxicity is to metabolize the inorganic arsenic into less acutely toxic organic species or they sequester arsenic into the vacuole with the aid of specific peptides (phytochelatins, PCs) and store it there. The arsenic complexes of these peptides synthesized by plants in response to arsenic exposure were only recently identified. Since these arsenic species are not covalently bound and contain the more labile trivalent arsenic their stability under standard extraction and storage conditions is limited. Arsenic-PC complexes are unstable under the influence of oxygen and disintegrate into the peptide and arsenite, which is then partially oxidized to arsenate. A successful extraction of these complexes is possible under acidic conditions at 1°C using fresh plant material. The separation of As-PCs is also hampered by their low stability under most separation conditions. Using size exclusion chromatography with ICP-MS detection does not provide conclusive proof, even ES-MS is not too helpful since the separation power of size exclusion chromatography is very limited. The complexes are successfully separated using reverse-phase chromatography with organic

**Figure 5** (A) Separation of newly identified arsenic species (3b, dimethylarsenothioyl acetic acid) in urine by using strong anion exchange chromatography (PRP X-100 Hamilton) coupled to ICP-MS for arsenic selective detection ( $m/z$  75) and parallel to ESI-MS for the protonated molecular mass ( $m/z$  197, 199) and major fragments ( $m/z$  137). (B) Gentle ionization at 100 V. (C) Molecular fragments of  $m/z$  107, 109 (As=S) and  $m/z$  91 (As=O) at 240 V fragmentor voltage. (Reproduced with permission from Hansen HR, Pickford R, Thomas-Oates J, Jaspars M, and Feldmann J (2004) 2-Dimethylarsenothioyl acetic acid identified in a biological sample: The first occurrence of a mammalian arsinothioyl metabolite. *Angewandte Chemie International Edition* 43(3): 337–340; © Wiley VCH.)

**Figure 6** Separation of As-PC complexes, ESI-MS data of As-PC species,  $m/z$  75 (arsenic) measured by parallel use of ICP-MS, separation with MeOH/formic acid gradient on a C18 ODS2 column (Reprinted with permission from Raab A, Feldmann J, and Meharg AA (2004) The nature of arsenic-phytochelatin complexes in *Holcus lanatus* and *Pteris cretica*. *Plant Physiology* 134: 1113–1122; © American Society of Plant Biologists.)

solvent (Figure 6). This separation method is well suited for the combination with ES-MS; it even improves the sensitivity of this technique somewhat, but is difficult to combine with ICP-MS. Combining reverse-phase chromatography online to an ICP-MS is possible, as done in this example, by addition of oxygen to the plasma and using a low-flow nebulizer for the ICP-MS with a flow splitter after the column to avoid too high amounts of organic solvent reaching the plasma of the ICP-MS.

## Emerging Techniques

Arsenic speciation in biological and environmental samples is anything but routine analysis. This is indicated in the small number of certified reference materials available with certified concentration of arsenic species. Attempt so far to produce standard reference materials for arsenosugars have failed and these are compounds that are considered as relatively stable arsenic species during extraction and separation procedures. The real challenge today is to identify unknown arsenic-containing compounds detected by LC-ICP-MS. For this purpose other techniques such as ES-MS or MALDI-MS are used to identify the molecular mass of the species. Multiple dimensional chromatographic separations (size exclusion chromatography + ion exchange + reverse phase) can help to solve the problem of co-eluting species for stable arsenic species as has been demonstrated successfully for the identification of a series of complex organoarsenicals in seaweed. FT-ICR-MS and qTOF-MS may bring a new dimension in the field of arsenic speciation, due to their accurate mass measurements using the mass defect of arsenic ( $m = 74.92159 \text{ g mol}^{-1}$ ) as an indicator of an

arsenic-containing compound. It is expected that traditional biochemical methods such as gel electrophoresis will find more use in this field, especially for the determination of arsenic-protein complexes. In addition to this new fleet of conventional techniques, X-ray absorption methods such as XANES or EXAFS can be utilized for the detection of very labile arsenic species directly in the unchanged organism, when they are present in concentrations of more than 20 mg per kg. It is just emerging that besides the wealth of organoarsenic species, many labile coordination species may occur, which may play a key role in the complex biochemistry of arsenic.

### Introduction

Asbestos minerals are subdivided into two classes, with six distinct types of fiber (Table 1). The serpentine group consists solely of chrysotile, popularly known as ‘white asbestos’, which once accounted for more than 95% of the asbestos used worldwide. Its crystal morphology is snake-like, with a tendency to form bundles. It is softer and more flexible than the other types of fiber. Chrysotile has a low iron content (~1.5%) and limited durability in the lung. The amphibole group consists of five chemically and morphologically diverse fibers primarily represented by crocidolite and amosite asbestos. Crocidolite, sometimes called ‘blue asbestos’, occurs as needle-like fibers that are high in iron content (36%) and are more durable than chrysotile in human lung.

Because of both natural and industrial processes, asbestos fibers have been widely dispersed and are present in the ambient atmosphere, the hydrosphere, in the soil of many areas, and in lung tissue after

occupational exposure. The establishment of asbestos fibers as carcinogenic and causing pulmonary and pleural diseases has led to the development of increasingly sensitive analyses for their detection and identification.

Optical microscopy (OM), polarized light microscopy (PLM), phase contrast microscopy, scanning electron microscopy (SEM), transmission electron microscopy (TEM), and scanning transmission electron microscopy (STEM) are the methods normally used for identification and quantification of the trace amounts of asbestos fibers that are encountered in the environment and lung tissue. Energy-dispersive X-ray spectrometry (EDXS) is used in both SEM and TEM for chemical analysis of individual particles, while selected-area electron diffraction (SAED) pattern analysis in TEM can provide details of the cell unit of individual particles of mass down to  $10^{-15}$  g. It helps to differentiate between antigorite and chrysotile. Secondary ion mass spectrometry, laser microprobe mass spectrometry (LMMS), electron probe X-ray microanalysis (EPXMA), and X-ray photoelectron spectroscopy (XPS) are also analytical techniques used for asbestos chemical characterization.

### Sampling Methods

Sampling should normally be undertaken using procedures described in International Standards Organization (ISO) documents.

Moreover, careful cleaning of all glass and plastic equipment like glassware or bottles is very important, especially in the preparation of suitable blank control filters. There may be serious social and economic consequences from the finding of a few fine fibrils.

### Airborne Dust Sampling

Airborne dust is placed on a filter by drawing through it measured volumes (minimum  $2\text{ m}^3$ ) of air. Usually filters with a pore diameter of 0.2 to  $1, 2\text{ }\mu\text{m}$  are used for collecting airborne dust during

**Table 1** Mineral types and chemical formulae of the asbestos varieties

Mineral group	Asbestos variety	Nominal chemical formulae <sup>a</sup>
Serpentine	Chrysotile	$\text{Mg}_3\text{Si}_4\text{O}_{16}(\text{OH})_8^b$
Amphibole <sup>c</sup>	Amosite	$(\text{Fe}^{2+}\text{Mg})_7\text{Si}_8\text{O}_{22}(\text{OH})_2$
Amphibole	Crocidolite	$\text{Na}_2\text{Fe}^{3+}(\text{Fe}^{2+}\text{Mg})_3\text{Si}_8\text{O}_{22}(\text{OH})_2$
Amphibole	Anthophyllite	$\text{Mg}_7\text{Si}_8\text{O}_{22}(\text{OH})_2$
Amphibole	Actinolite	$\text{Ca}_2\text{Fe}_2^{2+}\text{MgSi}_8\text{O}_{22}(\text{OH})_2$
Amphibole	Tremolite	$\text{Ca}_2\text{Mg}_5\text{Si}_8\text{O}_{22}(\text{OH})_2$

<sup>a</sup>Most natural asbestos can deviate a little from this nominal composition.

<sup>b</sup>Minor substitution of silicon by  $\text{Al}^{3+}$  may occur, and minor substitution of magnesium by  $\text{Al}^{3+}$ ,  $\text{Fe}^{2+}$ ,  $\text{Fe}^{3+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Mn}^{2+}$ , and  $\text{Co}^{2+}$  may also be present.

<sup>c</sup>In some varieties of amphibole the particular elements can be partially substituted by K, Li, Mn, Al, Cr, Ti, Pb, and Zn.

filtration. The type of filter used depends on the microscope used for further analysis.

### Water Sampling

Water samples are normally collected in clean, sterile, pretreated plastic bottles. If there is an excessive amount of suspended organic matter in the water, pretreatment of the samples using ultraviolet light and an ozone bubbler or sodium hypochlorite is necessary. Filtration is carried out using standard laboratory glassware, usually through a 25 mm-diameter filter of an appropriate material. The filter type depends on the microscope used for further analysis.

### Bulk Material Sampling

A solution or suspension must be prepared from bulk material or soil contaminated with asbestos fibers in a suitable liquid. In the case of contaminated soil a few kilograms should be taken as the minimum for analysis. Insoluble bulk samples of 2–3 g are ground to fine powder and mixed with distilled water. The way of filtration is the same as for simple water samples.

### Lung Tissue Sampling

Four to six grams of tissue blocks of formalin-fixed lung parenchyma are subjected to two different ashing techniques. To exclude any sampling errors, each tissue sample of peripheral disease-free lung is cut into 4–6 mm<sup>3</sup> cubes, which are mixed afterwards and randomly divided into two parts. One part is processed by wet ashing, the second one by hot ashing. In wet ashing 2–3 g lung tissue is digested in 45 ml of 13% solution with sodium hypochlorite (NaClO). In hot ashing it is heated in an oven at 600°C for 15 min. The ash is then suspended with distilled/deionized water and filtered as in water sampling. The hot ashing may have some drawback due to the fact that not all asbestos fibers can withstand a temperature of 600°C for 15 min and might break. Wet digestion cannot completely digest the tissue.

## Optical Microscopy

For OM examination tortuous-pore cellulose nitrate (CN), acetate, or mixed ester (CE) membrane filters with a pore size of 0.8 or 1.2 µm are recommended.

A low-power stereo binocular microscope is used to characterize and select suspected asbestos types fibers for further examination. Evaluation of the fibrous nature, color, luster, elasticity, flexibility, and other handling properties allows the detection and subsequent identification of asbestos in bulk materials at levels down to  $\sim 10 \text{ mg kg}^{-1}$ .

Microscope slides (72 mm × 25 mm × 0.8 mm approximately) and coverslips should be of the best optical quality and of the correct thickness for obtaining quality images (usually 0.17 mm). In the case of counting a particular fiber, an assumption has to be made about the cross-sectional profile of the fiber type; chrysotile is usually assumed to be cylindrical in shape, while the amphiboles are considered to have a thickness-to-width ratio of  $\sim 1.6:1$ . Discrimination of asbestos fibers using the morphology and refractive index in such cases is aided by prior identification of the fiber types present in the bulk material using PLM or other methods.

### Polarized-Light Microscopy

PLM is used to assess optical properties such as birefringence, pleochroism, and the extinction position. PLM can be used to differentiate asbestos from nonasbestos fibers.

### Phase-Contrast Optical Microscopy

Phase-contrast optical microscopy (PCOM) is used mainly for assessment of the refractive index in comparison with liquids of standard index. Next PCOM is widely used to measure fiber concentration. Before examination of the sample, acid treatment may be used to remove carbonates from cement matrices, or organic solvents may be necessary to remove plastic binder materials. OM operates at magnifications of only  $400\times$  and will not resolve fibers below 0.25 µm in diameter. Furthermore, PCOM cannot distinguish asbestos fibers from other fibers (e.g., gypsum, mineral wool, fiberglass, cellulose, etc.).

**Preparation of filters** Membrane filters of CE are placed on clean microscope slides and left to a short burst of acetone vapor. Then the filter is cleared by collapsing the filter structure. A drop or two of triacetin is applied to the filter surface, and a cover slip is carefully placed on it. The filter is ready for evaluation after a brief period of warming.

An optional procedure is to use an aqueous solution of dimethylformamide and acetic acid (so called Eukitt) for clearance of the filter structure, after which it is dried by warming at  $\sim 65^\circ\text{C}$  for a few minutes before a drop of Euparal resin is applied and the coverslip is gently placed on top.

**Fiber counting** Airborne fiber concentrations determined using OM refer strictly to those fibers that are longer than 5 µm, have diameters less than 3 µm, and have an aspect ratio of less than 3:1. The aspect ratio may be slightly different in some countries. All the

fibers are counted that are encountered during a systematic microscopic search of a small proportion of the filter. Thus PCOM is nonspecific for asbestos. The graticule (e.g., Walton–Beckett) is used to define a counting field and count fibers. Rules for split fibers, touching particles, fibers partially within the graticule, and other artifacts are also specified in the documentation of the method. Analysis using PCOM is limited to morphological observations and to some extent to refractive index assessment. Airborne fiber concentrations are calculated proportionately from the number of fibers counted, the effective area of the filter, the area searched, and the volume of air filtered and are usually expressed in fibers per milliliter or fibers per liter.

## Scanning Electron Microscopy

For SEM analysis a Nucleopore poly(carbonate) (PC) membrane filter (diameter 37 mm, pore size 0.2  $\mu\text{m}$ ) is used. After filtration each piece of the filter is coated with a very thin layer of gold. Routine SEM viewing is combined with an energy-dispersive X-ray microanalyzer (EDX). The particles and fibers are identified by their relative elemental peak intensities (based on magnesium, silicon, iron, and calcium), compared with their respective mineral standards placed in the computer bank (Figures 1–3).

### SEM Operating Conditions, Counting, Fiber Type Determination

SEM should be operated at magnifications of 2000–100 000 $\times$  with an acceleration voltage of 20–40 kV. Mineral fibers are counted on the screen. All inorganic particles having a length-to-width ratio at least 3:1 and parallel sides are defined as perfect fibers and counted. Cleavage fragments should not be counted. At a magnification of 5000 $\times$ , 13–25 inorganic fibers are counted or a minimum of 400 viewing fields are analyzed in order to reach an analytical sensitivity of 0.1 million fibers per gram for chrysotile. The fiber dimensions are measured with magnifications up to 100 000 $\times$ , and all inorganic fibers longer than 1  $\mu\text{m}$  are recorded.

EDX analysis is used to determine the fiber type. It should be carried out at higher magnifications (up to 50 000 $\times$ ). The absence of silicon or the presence of other elements such as aluminum or potassium can be used to demonstrate that a fiber is not asbestos, although care must be taken that there is no contamination of the fiber or of the EDX spectrum.

The proportions of the X-ray counts in the peaks of the spectra are not the same as the elemental proportions in the minerals.

**Figure 1** EDX spectrum of different types of asbestos fibers: (A) chrysotile; (B) crocidolite; (C) actinolite. The presence of an Au peak is the result of the sample preparation – filter coating with gold. The conditions of measurement: SEM with EDX; magnification, 2000–50 000 $\times$ , acceleration voltage, 20–30 kV.

## Transmission Electron Microscopy

Capillary PC membrane filters of maximum pore size 0.4  $\mu\text{m}$  or CE or CN membrane filters of maximum

**Figure 2** An example of an OM micrograph of asbestos fibers.

pore size  $0.8\text{ }\mu\text{m}$  are used for TEM analysis. Details of TEM are given in ISO standards.

#### TEM Filter Preparation

There are two ways of transferring the fibers from the filter to an electron-transparent membrane on a suitable TEM grid.

**Direct methods** In direct methods a PC filter, with fibers on it, is simply coated with carbon in a high-voltage carbon evaporation device. When CE or CN filters are used, they must be cleared and etched before coating with carbon. Care must be taken not to overheat the filter in the process by prolonging the arcing or by placing the filters too close to the arc as the filter may not then dissolve in the later stages of preparation. Small segments of carbon-coated filter,  $\sim 2$  or  $3\text{ mm}$  square, are cut from the filter and placed carbon side up on a TEM standard grid. Either this is placed on a Jaffe washer with a suitable solvent or a single drop of the solvent is carefully placed on the filter, where it is kept for  $\sim 30\text{ min}$ . Typical solvents are acetone for CE filters and chloroform or *N*-methyl-2-pyrrolidone for PC filters. TEM grids with the carbon film less than 75% of the grid squares should be rejected from the analysis.

**Indirect methods** Indirect methods are used where there is an excessive amount of organic fiber along with the asbestos, or some other soluble mineral fiber in an airborne sample. In these cases, treatment of the sample in a low-temperature oxygen plasma incinerator, or dissolution of the sample in a suitable solvent, followed by redeposition of the cleaned sample on a second filter can make the analysis

(A)

(B)

**Figure 3** Examples of SEM micrographs of asbestos fibers: (A) amphibole; (B) tremolite.

considerably easier. Subsequent preparation for TEM analysis follows the procedures of the direct method. Fiber counts for determination of regulatory asbestos fiber concentrations in the assessment of health risk will not usually be obtainable using indirect analysis methods. On the other hand, the indirect methods may be the only option for some types of environmental samples.

#### TEM Operating Conditions

TEM operating at an acceleration voltage of between 80 and 120 kV with a resolution of  $<1.0\text{ nm}$  and with a range of magnification from  $\sim 500\times$  to

$100\,000\times$  is routinely used. The viewing screen should have suitable calibrated markings to allow measurement of fibers directly on screen. The TEM should be capable of producing an electron diffraction (ED) pattern from a mineral particle of area  $0.6\,\mu\text{m}^2$  or less, selected from an image at  $20\,000\times$  magnification. A SAED aperture may be used to limit the area producing the pattern. A specimen holder that is capable of being tilted through  $+30^\circ$  to  $-30^\circ$  about an axis in the specimen plane combined with a rotation of  $360^\circ$  in the vertical axis is required for zone-axis ED.

The EDX system will normally be similar to that described for SEM for energy range and resolution. Additional specifications are required for asbestos analysis in that a background-subtracted sodium  $K\alpha$  peak from a 50 nm-diameter crocidolite fiber should have an integrated count rate of at least one count per second when irradiated by a probe of dimension 250 nm or smaller at an acceleration potential of 80 kV. The peak-to-ground ratio in this analysis should also be at least 1.0.

Analysis and inspection of SAED directly on screen is often enough for identification for chrysotile and a 'possible amphibole', but computer-aided measurement and analysis are required for detailed diffraction pattern indexing.

### Fiber Counting

The method of counting of asbestos fibers in TEM preparations differs from those of SEM or PCOM in that it does not rely on counting fibers within individual fields of view but depends on the systematic searching of complete grid openings in the TEM grid at a high magnification. The fiber lengths of interest are usually those longer than  $0.5\,\mu\text{m}$ , which for chrysotile fibrils implies a diameter range from 30 nm upward.

The rules for fiber or structure counting in TEM have gradually become more complicated with the recognition of the needs of different types, and matrices of different types containing various arrangements of fibers. In addition, there has been a need to recognize that the fiber numbers in such arrangements need to be counted carefully to provide reliable comparisons between samples and laboratories. It is necessary to read the ISO draft documents to count fibers properly.

### TEM Identification of Fibers

The identification of fibers as asbestos using TEM can be almost unambiguous, but it involves the most complex, difficult, and costly procedures. The process of identification involves three aspects of fiber

characteristics: morphology, crystal structure, and composition.

Fiber morphology is a very distinctive feature for chrysotile. Chrysotile fibrils are generally uniform in diameter, at  $\sim 25\,\text{nm}$ , and have a tubular structure that is almost unique and that appears, in a clear TEM image, as a lighter core to each dark fiber. Chrysotile is very susceptible to being damaged by the high energy of the electron beam, and so the tubular structure is easily destroyed and may not be visible. Similarly, chemical attack, even from quite dilute acid solutions, can leach magnesium from the fibrils and damage the tubular structure. The amphibole asbestos minerals are generally lath-shaped, parallel-sided, needle-like fibers. These usually show features such as extinction contours, multiple twin plane dislocations, and multiple chain defects (Wadsley defects), which are all characteristics of asbestos amphiboles rather than the more normal prismatic amphiboles. The amphiboles are very stable under an electron beam and are chemically very stable, and so they do not usually show any serious signs of damage.

EDX analysis in TEM is more definitive than in SEM and can be used to identify fiber chemistry quantitatively. The particles or fibers can be treated as thin films for the purposes of the calculation of atomic or mass fractions. This means that the effects of mass absorption and fluorescence can be ignored, although simple particle size effects need correction. In general the net integrated EDX peak areas can be treated as directly related to atomic or mass fractions with a proportionality factor derived from specific size ranges of similar reference minerals in an individual electron microscope. Such exact analysis is not always necessary, and simple comparison of spectra with those of reference minerals may be sufficient in many cases, although in this case the identification is recognized as being of a lower order of certainty than quantitative TEM analysis. Calibration of EDX equipment, as for SEM, is essential.

### TEM ED

Qualitative SAED consists of observation of the pattern of diffraction spots obtained on the TEM viewing screen from a randomly oriented fiber or particle. Such a pattern indicates that the material is crystalline. Chrysotile fibrils, with their cylindrical form, will usually give the same characteristic pattern, corresponding to a  $0.73\,\text{nm}$  spacing for (002) planes, and a layer line repeat of  $0.53\,\text{nm}$ , as well as streaking of the (110) and (130) reflections. These observations and measurements can be made directly from the screen if the appropriate calibrated screen

markings are available, but records should be made of a certain number of fibers in any sample. A range of other nonasbestos minerals can display a tubular morphology, including halloysite, palygorskite, talc, and vermiculite, and although their tubular forms are rare, their absence can only be proved using quantitative SAED or EDX.

SAED identification of amphibole asbestos fibers is only achieved in a formal sense by quantitative zone-axis interpretation, and even then it may not be possible in every case. Most randomly oriented fibers will show a diffraction pattern with a 0.53 nm layer spacing, but this is not by itself diagnostic for an amphibole. If multiple twinning, parallel to the *c* crystallographic axis, is present in the fiber, effectively resulting in several parallel crystals with different axial orientations, then apparently random spot distributions along the layer lines will be visible. If these observations can be made, then the fiber may be identified as an amphibole asbestos. If accurate measurement of the SAED pattern is to be made, then it is necessary to use an internal calibration standard such as a thin coating of gold on the underside of the TEM specimen. An Energy-dispersive spectrometer or electron probe X-ray microanalyzer, if present in the TEM, can be used as well.

## Scanning Transmission Electron Microscopy

STEM is a combination of scanning-transmission and transmission modes of operation in an electron microscope. Fibers are sought in the transmission mode at a magnification of 10 000–60 000 $\times$ ; this allows a maximum speed for the searching operation. Additionally, the ED pattern is generated in that mode. The scanning-transmission mode is used to measure the fiber dimensions at a magnification of up to 20 000 $\times$  on the monitor screen and to obtain the X-ray spectrum for elemental analysis.

## Secondary Ion Mass Analysis

The asbestos samples are prepared from a suspension in hexane spotted on indium foil. Ion images (from  $\sim 150\ \mu\text{m}$ ), mass spectra and the energy distribution of positive secondary ions are obtained. Either silicon or magnesium positive ion images may be used to indicate the asbestos fibers.

## X-Ray Photoelectron Spectroscopy

The asbestos samples are mounted with double-sided tape. The area of analysis is 600  $\mu\text{m}$ . An electron

flood gun operating at a few electronvolts and a nickel mesh covering the sample/sample holder arrangement are used for charge compensation. The Mg/Si concentration is calculated to recognize the fiber type.

## Laser Microprobe Mass Spectrometry

LMMS uses a pulsed beam of photons to evaporate a sample in a small region, as small as 0.5  $\mu\text{m}$  in diameter. A fraction of the evaporated atoms is ionized by the laser beam, accelerated to a kinetic energy of 3 keV, and then analyzed using a time-of-flight mass spectrometer. The instrument provides detection of all elements and isotopes, with detection limits in microgram per gram range from a total sample consumption of 0.1 pg per spectrum. Absolute detection limits are thus in the femtogram range. Quantitative analysis is based on the use of sensitivity factors, and the accuracy is limited to  $\sim 20\%$  relative. A sample for transmission geometry LMMS must be in the form of a particle or a thin film. Typical applications include analysis of particles as small as 200 nm in diameter.

## General Analytical Considerations

### Confidence Level of Identification

As is clear from the foregoing sections, there is a wide array of different observations and measurements available for every single fiber. Electron microscopy can be used to detect very thin fibers and allows us to identify different types of fibers. Therefore, nonasbestos fibers can be eliminated from the measurement. The disadvantage of the STEM method lies in the time and cost consideration. OM has more drawbacks, for example, a limited resolution. To be identified as chrysotile, fibers must exhibit their characteristic morphology and also contain magnesium and silicon, whereas anthophyllites have additional peaks of calcium or iron in their X-ray spectra. In several samples the identity of chrysotile and amphibole fibers is confirmed qualitatively using TEM (at 80 kV, magnification 20 000 $\times$ ) and SAED.

In counting thin chrysotile fibers, the SEM method may produce lower results than the TEM technique, but for coarser amphibole fibers such an effect is not likely. A large number of amphibole and nearly all chrysotile fibers are undetectable using OM. Definitive identification of a chrysotile can only be made if a characteristic SAED pattern is recorded for a tubular morphology fiber and the EDX spectrum is quantitatively consistent. Not all these elements may be either necessary or desirable for any or all fibers in every sample. This means that the level to which each fiber has been identified needs to be recorded to

**Table 2** Classification of fibers with tubular morphology

TM	Tubular morphology, not sufficiently characteristic for classification as chrysotile
CM	Characteristic chrysotile morphology
CD	Chrysotile SAED pattern
CQ	Chrysotile composition by quantitative EDXS
CMQ	Chrysotile morphology and composition by quantitative EDXS
CDQ	Chrysotile SAED pattern and composition by quantitative EDXS
NAM	Nonasbestos mineral

**Table 3** Classification of fibers without tubular morphology

AD	Amphibole fiber by random orientation SAED (shows layer pattern of 0.53 nm spacing)
AX	Amphibole by qualitative EDX. Spectrum has elemental components consistent with amphibole
ADX	Amphibole by random orientation SAED and qualitative EDX
AQ	Amphibole quantitative EDX
AZ	Amphibole by one zone-axis SAED pattern
ADQ	Amphibole by random orientation SAED and quantitative EDX
AZQ	Amphibole by one zone-axis SAED pattern and quantitative EDX
AZZ	Amphibole by two zone-axis SAED patterns with consistent interaxial angle
AZZQ	Amphibole by two zone-axis SAED patterns with consistent interaxial and quantitative EDX
NAM	Nonasbestos mineral
UF	Unidentified fiber

avoid differences and ambiguities in results and to allow interlaboratory comparisons to be made. **Table 2**, from the draft ISO standard, illustrates the different levels of possible identification that may be made for tubular fibers found in environment samples. It is important to recognize also the influence of the chemical history of each fiber in the identification since the chemistry of chrysotile is not stable, even in the mildest of acid conditions. The amphibole asbestos minerals have an even more complicated hierarchy of identifications based upon four levels of SAED analysis and three levels of EDX analysis (**Table 3**). The resulting 11 possible classifications for any fiber are made even more complicated by the need to incorporate the distinction between asbestos and nonasbestos varieties of the amphiboles.

XPS, EPXMA, and LMMS are especially used to characterize the surface of modified asbestos fibers. Alteration of asbestos surfaces by either acid leaching or deposition of a chemical coating reduces the hazards associated with asbestos exposure.

### Fiber Counting: Accuracy and Precision

There is no independent method available to determine the accuracy of fiber counts, although mass

estimates based upon fiber counts may be traceable to other mass estimates of standards. All the quantitative analyses described here rely upon procedures of fiber counting that have been shown to involve a series of uncertainties that require careful consideration in the interpretation of results.

If it is assumed that both the deposition of fibers on the filter and the selection of fields for counting are random, then there will be a variability in the results that can be described by a Poisson distribution. For fiber counts of  $\sim 50$  this leads to 95% confidence intervals in the results of  $\sim \pm 15$  (30%) and a coefficient of variation of  $\sim 15\%$ , although for smaller fiber counts the variability will be much larger. In addition to this variability there is an unavoidable degree of nonuniformity of the asbestos deposit on the filter. There is also subjective variation between microscopists in interpretation of fiber structures and in their ability to detect and identify fibers. Overall counting performances cannot then be expected to produce a coefficient of variation better than  $\sim 25\%$  for counts of  $\sim 50$  fibers.

Good quality control procedures are essential to keep these subjective variations to acceptably low levels, and satisfactory performance in both internal and external fiber counting exchange schemes is usually recommended by regulatory authorities.

### Sensitivity and Detection Limits

The analytical sensitivity of fiber counting methods is usually accepted as being a single fiber found in the course of a standard search. With conventional methods, this may translate to airborne fiber concentrations of  $\sim 0.1$  fiber per liter in ambient samples of  $\sim 1 \text{ m}^3$ , or  $\sim 1000$  fibers per liter for water samples of  $\sim 1 \text{ l}$ .

The detection limits are determined by the number of fibers in suitably prepared blank filters and by the random nature of the filter and of the search. In some electron microscopy preparations, where no fibers are found in the blank controls, the detection limit has been taken as 3.69 times the sensitivity (the upper 95% confidence limit for zero in a Poisson distribution). Otherwise, as in PCOM, where a nonzero blank control is common, a higher detection limit prevails. Thus a series of blank filters might produce an average fiber count of five fibers in a standard analysis, which for routine air samples ( $\sim 0.5 \text{ m}^3$ ) could translate into a detection limit of  $\sim 0.01$  fibers per milliliter.

## Glossary

Amphibole	Group of rock-forming ferromagnesium silicate minerals, closely related in crystal form and composition.
The asbestos minerals	Naturally occurring fibrous, crystalline, silicate minerals belonging to the serpentine and amphibole groups.
Membrane filters	Filters of cellulose esters or polycarbonate with pore sizes of 0.2–1.2 µm. Used for filtration of asbestos-bearing solutions or suspensions.
Aspect ratio	Ratio of length to width of a particle.
Electron diffraction	Technique in electron microscopy by which the crystal structure of a specimen is examined.
Energy-dispersive X-ray analysis	Measurement of the energies and intensities of X-rays using a solid-state detector and multichannel analyzer system.
Fiber	Elongated particle that has parallel or stepped sides; for the purpose of ISO, a fiber is defined to have an aspect ratio equal to or greater than 5:1 and a minimum length of 0.5 µm.
Selected-area electron diffraction	Technique in electron microscopy in which the crystal structure of a small area of a sample is examined.
Serpentine	Group of common rock-forming minerals having the nominal formula.
Twinning	Occurrence of crystals of the same species joined together at a particular mutual orientation, such that the relative orientations are related by a definite law.
Zone-axis	Line or crystallographic direction through the center of a crystal that is parallel to the intersection edges of the crystal defining the crystal zone.

### Introduction

Atomic absorption spectrometry (AAS) is a technique in which free gaseous atoms absorb electromagnetic radiation at a specific wavelength to produce a corresponding measurable signal. The absorption signal is proportional to the concentration of the free atoms present in the optical path.

The physical phenomenon, first observed by Foucault in 1849, was converted into a popular analytical technique by Walsh essentially with the development of the hollow cathode lamp as the source of spectral energy for absorbance measurements. This permitted relatively cheap atomic absorption spectrometers to become available.

This article examines the basic theory of energy states of atoms, the quantitative analysis by atomic absorption, and the main components of the atomic absorption spectrometer.

### Atomic Structure and Spectra

For a strong absorption of electromagnetic radiation the lower energy state of the analyte atom must be highly populated and all selection rules must be observed. In order to examine these criteria, both energy states involved in the transition of the atom should be known. The upper energy state is not known for all elements, but even in such cases important conclusions may be drawn from the spectral term of the lower energy state, which is usually the ground state of the atoms. Therefore, the derivation

of the electronic configuration of the atoms will be discussed.

The distribution of electrons in an atom is governed by two atom-building principles:

- The orbitals (energy levels) are occupied in order of increasing orbital energy.
- All electrons in an atom must be present in a different microstate, i.e., the electrons must be distinguishable at least in one of their quantum numbers (Pauli's exclusion principle).

The principal quantum number  $n$  defines the shell in which the electron is located; the maximum number of electrons taken up in a shell is  $2n^2$ . Within the shell the electrons reside in orbitals of different symmetry, described by the angular momentum quantum number  $l$ , which can take values of 0, 1, 2, ...,  $n$ . An orbital can accommodate up to two electrons having opposite spins. Each of the electrons is characterized by the inner quantum number  $j$  that can take values of  $l \pm 1/2$ .

The general atom-building principles (a) and (b) are supplemented by rules that depend on the magnetic and chemical behavior of the elements:

- The special stability of the electronic configuration of the noble (inert) gases allows the classification of electrons into two main groups: core electrons, present in a noble gas shell, and valence electrons, present in subshells. Core electrons are not involved in chemical reactions and do not contribute to the generation of spectroscopic terms, which means that the elucidation of electronic configurations is greatly simplified, e.g.,

- The special stability of the half-filled and completely filled d and f subshells has the consequence that the configurations predicted by the rules (a) and (b) only are less stable than the configuration

predicted by the supplementary rule (d):

$$\text{Cr}(0) = [\text{Ar}]4s^23d^4 = [\text{Ar}]4s^13d^5 = [\text{Ar}]3d^54s^1$$

$$\text{Cu}(0) = [\text{Ar}]4s^23d^9 = [\text{Ar}]4s^13d^{10} = [\text{Ar}]3d^{10}4s^1$$

$$\text{Gd}(0) = [\text{Xe}]6s^24f^8 = [\text{Xe}]6s^24f^75d^1 = [\text{Xe}]4f^75d^16s^2$$

After applying the atom-building principles and the additional rules (c) and (d), the configuration obtained often does not contain the subshells in order of increasing principal quantum number. Standardization is easily achieved by altering the position of the subshells in the written configurations. A physicochemical reason for the natural order of principal quantum number  $n$  is given by the fact that the electrons with higher  $n$ -values ionize first.

In order to elucidate the spectroscopic terms belonging to a given electronic configuration, the first step is to ascertain the electron configuration using the atom-building principles (a), (b), and the additional rules (c), (d). The number of Pauli-allowed combinations  $N_{\text{ms}}$  (number of microstates) should be also calculated so that the correctness of the terms obtained can be checked. For a subshell partly filled with electrons,  $N_{\text{ms}}$  is given by the expressions:

$$N_{\text{ms}}(nl^N) = \frac{1 \times 2 \times \dots \times (4l+2)}{(1 \times 2 \times \dots \times N)(1 \times 2 \times \dots \times (\langle 4l+2 \rangle - N))} \quad \text{for } 1 \leq N \leq (4l+1) \quad [1]$$

where  $N$  is the number of electrons in the orbitals.

$$N_{\text{ms}}(nl^{(4l+2)}) = 1 \quad \text{for completely filled shells} \quad [2]$$

If more than one partially filled subshell is present, the product of the  $N_{\text{ms}}$  values calculated for all these subshells gives the number of microstates of the configuration:

$$N_{\text{ms}}(nl^N, n'l'^{N'}, \dots) = N_{\text{ms}}(nl^N) \times N_{\text{ms}}(n'l'^{N'}) \times N_{\text{ms}}(\dots) \quad [3]$$

An example is the excited configuration of Be, ..., Ba ( $s^1p^1$ ):

$$N_{\text{ms}} = \frac{1 \times 2}{1 \times (1)} \times \frac{1 \times 2 \times \dots \times 6}{1 \times (1 \times 2 \times \dots \times 5)} = 2 \times 6 = 12$$

Another example is the ground configuration of Gd ( $6s^24f^75d^1$ ):

$$\begin{aligned} N_{\text{ms}} &= 1 \times \frac{1 \times 2 \times \dots \times 14}{1 \times 2 \times \dots \times 7 \times (1 \times 2 \times \dots \times 7)} \\ &\quad \times \frac{1 \times 2 \times \dots \times 10}{1 \times (1 \times 2 \times \dots \times 9)} \\ &= 1 \times 3432 \times 10 = 34\,320 \end{aligned}$$

These examples show clearly that the number of microstates is small for a few valence electrons in the  $s$  and  $p$  subshells but becomes large for more electrons in the  $d$  and  $f$  subshells.

**Table 1** lists the electronic configurations and some related properties of the elements. In the selection of the elements, two criteria were observed:

- The resonance line, i.e., the line due to the transition between the ground state and the lowest excited state, must be situated within the spectral range of standard atomic absorption spectrometers (190–860 nm).
- The characteristic concentration, i.e., the concentration yielding 1% absorption (or 0.0044 absorbance), must be lower than  $100 \text{ mg l}^{-1}$ .

The excitation energies of the noble gases, the halogens, and sulfur are so high that the corresponding resonance lines are situated in the vacuum ultraviolet (UV) region, where oxygen intensively absorbs. In some cases this nonspecific absorption can be reduced by the use of a shielding gas (e.g., Ar or  $\text{N}_2$ ).

The elements can be classified into four spectrochemical groups on the basis of  $E_1$  and  $D_0$ : (a)  $E_1 \geq 7.0$  and  $D_0 \leq 4.2$ ; (b)  $E_1 \leq 7.0$  and  $D_0 \leq 4.2$ ; (c)  $E_1 \leq 7.0$  and  $D_0 \geq 4.2$ , and (d)  $E_1 \geq 7.0$  and  $D_0 \geq 4.2$ .

The number of microstates  $N_{\text{ms}}$  resulting from the corresponding electron configuration varies between one for electron configurations with closed valence shells and 34 320 for Gd.  $N_{\text{ms}}$  can serve as a measure of the complexity of the atomic absorption (and emission) spectra. An element with a large number of microstates also has a large number of spectroscopic terms and atomic lines, because of the many different term combinations possible.

According to the selection rules, transitions are allowed for which the angular momentum quantum number  $l$  increases by one unit, while the principal quantum number can change by any amount. The allowed transitions of the electrons can be compiled in term series in which the principal quantum number  $n$  precedes the term symbol as a number. The series in which  $l = 0, 1, 2, 3$  are designed by the letters  $s, p, d, f$ . Through the spin of the electrons and the associated magnetic field, splitting of the energy levels takes place, described by the inner quantum number  $j$ , which results in a fine multiplet structure of the spectral lines.

The energy levels can only absorb well-defined amounts of energy, i.e., they are quantized according to the symmetry rules. The most stable electronic configuration of an atom that has the lowest energy is the ground state. For example, the electronic configuration of the sodium atom is  $1s^22s^22p^63s^1$  (ground state with energy  $E_0$ ). The transition

Table 1 Continued

Z	Symbol	Electron configuration	$N_{ms}$	$E_1$ (eV)	$D_0$ (eV)
78	Pt	[Xe]4f <sup>14</sup> 5d <sup>9</sup> 6s <sup>1</sup>	20	9.0	4.09
79	Au	[Xe]4f <sup>14</sup> 5d <sup>10</sup> 6s <sup>1</sup>	2	9.225	2.30
80	Hg	[Xe]4f <sup>14</sup> 5d <sup>10</sup> 6s <sup>2</sup>	1	10.44	2.29
81	Tl	[Xe]4f <sup>14</sup> 5d <sup>10</sup> 6s <sup>2</sup> 6p <sup>1</sup>	6	6.108	—
82	Pb	[Xe]4f <sup>14</sup> 5d <sup>10</sup> 6s <sup>2</sup> 6p <sup>2</sup>	15	7.416	3.96
83	Bi	[Xe]4f <sup>14</sup> 5d <sup>10</sup> 6s <sup>2</sup> 6p <sup>3</sup>	20	7.289	3.50
92	U	[Rn]5f <sup>3</sup> 6d <sup>1</sup> 7s <sup>1</sup>	3640	—	7.87

Elements with resonance lines between 193.70 nm (As) and 852.11 nm (Cs) and characteristic concentrations  $c_{1\%} < 100 \text{ mg l}^{-1}$  were selected. Z is the number of electrons,  $N_{ms}$  the number of microstates,  $E_1$  the first ionization energy, and  $D_0$  the bond dissociation energy of the corresponding monoxide MO.

**Figure 1** Partial Grotrian diagram for sodium. (Reprinted from Robinson JW (1990) *Atomic Absorption Spectroscopy* by courtesy of Marcel Dekker Inc.)

between the 3s orbital and a p orbital can be realized by absorption of light of definite wavelength, as illustrated in the partial term (Grotrian) diagram of sodium shown in **Figure 1**. For the sake of clarity, many of the upper-state transitions are omitted.

The absorption lines due to the transition between the ground state and the lowest excited state of the atom are referred to as the resonance lines. Sometimes alternate lines are used in AAS to extend the working range to higher concentrations or to avoid spectral interferences (seldom in AAS).

To realize the first transition 3s → 3p, the frequency of the incident light ( $\nu_1$ ) should correspond to:

$$\nu_1 = \frac{E_1^* - E_0}{h}$$

where  $E_1^*$  is the energy of the first excited state,  $E_0$  is the energy of the ground state, and  $h$  is Planck's constant.

The intensity of the incident light will decrease as part of it will be absorbed by the atoms. The electron

resides in the excited state  $E_1^*$  for only  $10^{-7}$  to  $10^{-9}$  s, after which it returns to its stable ground state by emitting radiant energy of the same frequency  $\nu_1$ .

## Spectral Line Width

It follows from the above discussions that the spectral width of the light emitted by the atoms should be infinitely small. Correspondingly, the atoms should absorb only light of a definite frequency. Actually, a band of intensity distribution close to the Gaussian (**Figure 2**) is emitted or absorbed, respectively. The profile of the line is characterized by the central frequency  $\nu_0$ , the peak intensity  $I_p$ , and the frequency distribution with a width of  $\Delta\nu_{\text{eff}}$ , generally quoted as the full-width at half-maximum  $I_{p/2}$  (FWHM).

The broadening of the spectral lines is due to three reasons:

1. The natural broadening depends on the lifetime of the excited state and is usually in the range  $10^{-5}$  to  $10^{-3}$  nm.
2. The Doppler broadening ( $D$ ) is proportional to the absolute temperature ( $T$ ):  $D \sim \sqrt{T}$ . It is due to the random movement of the atoms and leads to a symmetrical broadening of the spectral line. Within the range 20–3000°C, the Doppler broadening varies between  $10^{-5}$  and  $10^{-2}$  nm.
3. The collisional broadening depends on the number of collisions of the emitting or absorbing atoms with other particles. After each collision the energy of the atom changes resulting in line broadening. In most cases the energy of the atom decreases after collision, leading to an additional shift of the line profile. The shift is proportional to the pressure of the surrounding particles. A pressure change in the range 0.01–760 mm Hg leads to a collisional broadening of  $10^{-6}$  to  $10^{-2}$  nm.

The spectral line broadening is a sum of the natural, Doppler, and collisional broadening; however, the natural broadening is relatively small and can be neglected.

**Figure 2** Profile and characteristics of a spectral line.

## Quantitative Analysis by Atomic Absorption

The atomic absorption process consists of the following steps: light at a specific wavelength of initial intensity  $I_0$  passes through the absorbing layer containing ground-state analyte atoms. The initial light intensity decreases by an amount determined by the atom concentration in the absorbing layer and the reduced intensity  $I$  is measured. The absorbance  $A$ , i.e., the logarithm of the ratio between the initial light intensity and the reduced intensity, is proportional to the concentration of free analyte atoms in the absorbing layer according to the Beer–Lambert law:

$$A = \log I_0/I = abC$$

where  $a$  is the absorption coefficient, a constant characteristic for the absorbing species at a specific wavelength,  $b$  is the length of the absorbing layer, and  $C$  is the concentration of the absorbing species.

Several related terms are used to define the amount of light absorption: the transmittance  $T = I/I_0$ , also expressed in percentage terms,  $T\% = 100 \times I/I_0$  and the percent absorption  $A\% = 100 - T\%$ , which is the complement of percent transmission.

For analytical purposes the absorbance  $A$  is mostly used, which is proportional to the concentration of free gaseous atoms of the analyte under definite experimental conditions. The formation of free gaseous atoms from the analyte species present in the sample solution involves several processes, e.g., desolvation, volatilization, dissociation of the chemical compounds. The efficiency of these processes for the given experimental conditions is included in the calibration equation. The calibration relationship is established by measuring the absorbances of standard solutions containing known amounts of analyte and plotting the absorbance data against concentration. Over the region where the Beer–Lambert law is

obeyed, the calibration yields a straight line. A deviation from linearity is usually observed at absorbances greater than 0.5–1.0.

After calibration is established, the absorbance of solutions of unknown analyte concentrations may be measured and the concentration may be determined from the calibration curve.

## Typical Performance Characteristics of AAS

### Sensitivity and Characteristic Concentration

The sensitivity of the AAS determination is defined by the slope of the calibration curve in its initial straight part. A convenient characteristic of the sensitivity is the characteristic concentration – the analyte concentration that produces 1% absorption (or 0.0044 absorbance) signal. The characteristic concentrations of the elements for flame atomizers are between 0.01 and 10 mg l<sup>-1</sup>, for electrothermal atomizers – ~2–3 orders of magnitude lower. Factors affecting the sensitivity are: the oscillator strength (the probability) of the corresponding electron transition, the type of the atomizer – flame or electrothermal – and the efficiency of atomization.

### Detection Limits

The term detection limit incorporates a consideration of both signal size and baseline noise to give an indication of the lowest concentration of an element that can be measured with a given statistical certainty. According to IUPAC, the detection limit is defined as the concentration that will give an absorbance signal three times the magnitude of the baseline noise. The latter can be statistically quantitated typically by making 10 or more replicate measurements of the baseline absorbance signal of an analytical blank, and determining the standard deviation of the measurements. The detection limit is then defined as the concentration that will produce an absorbance signal three times the standard deviation of the blank.

Practically, routine analytical work should be limited to concentrations several times higher than the detection limit.

### Precision and Accuracy

The precision is typically 0.3–1% at absorbances larger than 0.1 or 0.2 for flame atomization and 1–5% for electrothermal atomization. The accuracy is generally limited by random error and noise to 0.5–5%, but may be affected by systematic errors due to spectral and chemical interferences.

## Instrumentation

The basic components of an atomic absorption spectrometer are schematically presented in Figure 3 and are discussed below:

1. The light source emits the atomic lines of the analyte element. The source radiation is modulated to provide a means of selectively amplifying the light emitted by the source lamp and discriminating the emission from the sample cell.
2. In the sample cell an atomic vapor must be generated. To this purpose the sample is introduced into the atomizer – a flame system or electrically heated furnace aligned in the optical path of the spectrometer.
3. A monochromator is used to disperse the various wavelengths of light that are emitted from the source and to isolate the particular line of interest. This allows a selected element to be determined in the presence of others.
4. The wavelength isolated by the monochromator is directed onto the detector. This is normally a photomultiplier tube producing electrical current proportional to the light intensity.
5. The electrical current is then amplified and processed by the instrument electronics to produce the readout signal which is a measure of the light attenuation occurring in the sample cell.

## Optical Systems

Optical systems corresponding to single-beam or double-beam spectrometers can be distinguished in

**Figure 3** Principle of construction of atomic absorption spectrometers. (A) Single-beam spectrometer with electrically modulated lamp radiation; (B) double-beam spectrometer with reflection and splitting of the primary radiation by a rotating, partially mirrored quartz disk (chopper). 1 – radiation source, 2 – sample cell (atomizer), 3 – monochromator, 4 – detector, 5 – electronics and readout (by permission of Wiley-VCH from Welz B and Sperling M (1999) *Atomic Absorption Spectrometry*, 3rd, completely revised edition. Weinheim: Wiley-VCH).

AAS. In single-beam instruments (Figure 3A), all measurements are based on the varying intensity of a single beam of light in a single optical path. These instruments have fewer optical components and thus have the advantage of low light attenuation. Therefore, they do not need a high electronic amplification of the signal. Single-beam atomic absorption spectrometers provide, however, no means to compensate for instrumental variations during the analysis, such as drift in source intensity.

In double-beam systems (Figure 3B), the light from the radiation source is split by a beam splitter into two beams – a sample beam directed through the sample cell and a reference beam directed around the sample cell. The reference beam serves as a monitor of the lamp intensity and the response characteristics of electronic circuitry. The observed absorbance, determined from the ratio of sample beam and reference beam readings, is thus free of effects due to drifting lamp intensities.

There are several alternative system designs that combine the advantages of double-beam and single-beam optical systems. One such design uses two mechanically adjusted mirrors to alternately direct the entire output of the source through either the sample path or a reference path.

By utilizing the Zeeman effect it is also possible to obtain an (optical) single-beam instrument with double-beam characteristics. When the magnetic field at the atomizer is switched on, the analyte ions cannot absorb the radiation from the source, while they can absorb normally when the magnetic field is switched off. Since the radiation with and without magnetic field has the same intensity, drifts in the source or detector are eliminated, as with a double-beam instrument.

## Radiation Sources

As radiation sources in AAS, those line sources are mainly used that emit the spectral lines of one or more elements. Line sources make it possible to use conventional instead of high-resolution monochromators, as the monochromator only has to isolate the line of interest from other lines (mainly lamp fill gas lines). Hollow cathode lamps and electrodeless discharge lamps are the main types of lamps employed.

Hollow cathode lamps (HCLs) are available for most of the elements determinable by AAS. Figure 4 shows the schematic diagram of an HCL.

The cathode of the lamp is a hollow cylinder of the metal to be determined. The anode and cathode are sealed in a glass cylinder normally filled with either Ne or Ar at low pressure. At the end of the glass

**Figure 4** Schematic diagram of a hollow cathode lamp. (Reprinted from Robinson JW (1990) *Atomic Absorption Spectroscopy* by courtesy of Marcel Dekker Inc.)

cylinder is a window transparent to the emitted radiation. When an electrical potential is applied between the anode and cathode, some of the fill gas atoms are ionized. The positively charged fill gas ions, accelerated through the electrical field, bombard the negatively charged cathode by dislodging (sputtering) metal atoms from it. Sputtered metal atoms are then excited to emit their spectrum through kinetic transfer by impact with fill gas ions.

In electrodeless discharge lamps (EDLs) a small amount of the metal to be determined or its volatile compound is sealed inside a quartz bulb placed inside a small radio-frequency (RF) generator. When power is applied to the generator, an RF field is created and a low-pressure plasma is generated which vaporizes and excites the atoms inside the bulb, causing them to emit their spectrum. EDLs are particularly advantageous for volatile elements and for elements emitting in the far UV range.

Continuum sources emit radiation continuously distributed over a greater wavelength range. In AAS, continuum sources are used mainly for background measurements and correction. The deuterium lamp emits radiant power in the short wavelength range from  $\sim 190$  to  $330$  nm, while the halogen lamp covers the spectral range above  $300$  nm.

### The Monochromator System

The major components of the monochromator are the slits and the dispersion element. The source radiation falls on the entrance slit and is directed to the dispersion element that is based on either reflection or refraction. Only the light of the desired wavelength passes through the exit slit to fall onto the detector. The monochromator plays an important role in determining the baseline noise in an atomic absorption spectrometer since it defines the amount of light energy reaching the detector.

### Detection of Radiation

The photomultiplier tube is a radiation detector using the photoelectric principle. The radiation falling on a photocathode causes the emission of primary electrons that are released into the surrounding vacuum. As a result of the applied voltage between the electrodes (dynodes), the primary electron is accelerated so that when it strikes a dynode several secondary electrons are emitted, leading to a cascade effect.

### Atomizers

As discussed above, for the measurement of atomic absorbance free ground-state atoms must be present in the sample cell. With the exception of mercury, free atoms do not exist in a stable form at room temperature. The atomizer is the place where free atoms of the analyte are created. The number of free atoms depends on the dynamic equilibrium between the number created and the number lost, e.g., by compound formation and ionization. The bond dissociation energy of the corresponding monoxide  $D_0$  and the first ionization energy  $E_1$  (shown in Table 1) are among the factors affecting this equilibrium.

The choice of the suitable atomizer for a given analytical task depends on the concentration of the analyte in the sample, the analyte itself, and the amount of sample available. In the following, the main atomizer types will be briefly presented.

**Flame atomizer** The flame is the oldest method of obtaining a population of free atoms in an atomic absorption instrument. A liquid sample is nebulized to form an aerosol of fine liquid droplets, which is introduced into the base of the flame where the solvent evaporates. Higher in the flame the sample residue decomposes and free atoms are generated.

In routine flame AAS work only the air/acetylene flame and the nitrous oxide/acetylene flame, both premixed laminar flames, are used. The combustion of acetylene with nitrogen oxide gives a considerably higher temperature ( $3000$  K) than the air/acetylene reaction ( $2500$  K).  $N_2O$  is kinetically very stable at room temperature but reacts with  $C_2H_2$  very fast at elevated temperatures by releasing its own chemical energy of  $83.8 \text{ kJ mol}^{-1}$ , thus giving a higher flame temperature. Furthermore, only  $5 \text{ mol } N_2$  per mol of  $C_2H_2$  must be heated to the corresponding temperature, compared to  $10$  for the air/acetylene mixture as detailed in the reactions below:

The main restriction of the flame atomizer is the sensitivity, generally limited to the  $\text{mg l}^{-1}$  range. There are several attempts to increase the sensitivity of flame AAS, e.g., by locating a quartz, silica, or metal tube in the flame. An increase in the detection limits of more than one order of magnitude may be achieved in this way. This strongly increased power of detection is mainly due to the prolonged residence time of the analyte atoms in the absorbing layer.

**Graphite tube atomizer** The main type of electrothermal atomizer is the graphite tube. A definite volume of a liquid sample is introduced into the graphite tube which is subsequently gradually and step-wise heated to increasing temperatures according to a preselected program normally including drying, pyrolysis, atomization, clean out, and cooling steps. During the drying step low-temperature heating is applied to evaporate the solvents from the sample. The ideal temperature is just below the boiling point of the solvent to prevent sputtering of the sample. The aim of the pyrolysis step is to break down or evaporate the matrix prior to atomization by heating to the highest possible temperature without losses of the analyte element. The atomization step aims at the creation of free gaseous atoms of the analyte. The atomization temperature depends on the type of both analyte and sample. The clean-out and cooling steps serve to prepare the graphite tube for the next run.

The graphite tube atomizer operates under spatially and temporally nonisothermal conditions. The analyte atoms volatilized from the tube wall come into a cooler gas, so that molecular species may be formed, leading to chemical interferences. L'vov suggested the sample to be deposited onto a small graphite platform aligned in the central part of the graphite tube. The platform is heated primarily by radiation from the walls, so that there is a time lag between heating of the tube and the platform. The platform reaches the atomization temperature when the tube wall and the gas have already reached (or almost reached) equilibrium. The analyte atoms are thus volatilized in a gas with a temperature higher than the equilibrium, so that chemical interferences are diminished.

**Quartz tube atomizer** Some elements like antimony, arsenic, bismuth, lead, tin, can be vaporized as molecules (e.g., hydrides) by chemical reaction at room temperature. For this purpose a reductant solution ( $\text{NaBH}_4$ ,  $\text{SnCl}_2$ ) is added to the sample solution and the obtained gaseous hydrides are transported to the quartz tube atomizer (hydride

generation AAS). The same arrangement can be used for mercury, which upon reductant addition is released as atomic vapor. In this case the quartz tube acts as a sample cell only (cold vapor AAS).

### Sample Introduction and Sample Pretreatment

Sample introduction and sample pretreatment are still limiting factors in AAS, determining the selectivity and sensitivity of the AA analysis. In AAS, typically liquid samples are analyzed. Nevertheless, several sample introduction systems have been developed for the direct atomic absorption analysis of solid samples avoiding sample dissolution, which is labor intensive and suffers risks of both contamination and losses. Solid samples in the form of powders, slurries, etc., are mostly analyzed in electrothermal atomizers.

Another approach offering a variety of rapid, reliable, and economic ways for sample pretreatment and sample introduction in AAS is the online coupling of flow injection systems with both flame and electrothermal AAS techniques. Such integrated systems have made a great progress in recent years by providing automated operation avoiding time-consuming manual work and enhancing accuracy and precision.

### Introduction

Atomic absorption spectrometry (AAS) is a very sensitive method of elemental analysis, allowing the determination of metals in a variety of samples at the picogram level. It has been used for thousands of applications involving a wide diversity of samples. The atomic absorption phenomenon involves a measurement of the reduction of the intensity of optical radiation subsequent to its passage through a cell containing gaseous atoms. Modern instrumentation for AAS typically consists of a light source called a hollow cathode lamp (HCL), which emits specific wavelengths of light that are ideally only absorbable by the analyte; an 'atom cell', which serves to convert the samples into gaseous atoms that can absorb light from the HCL; a 'detection system' that serves to isolate and quantify the wavelengths of interest; and a computer system to control instrument operation and collect and process data. Most commonly, samples are converted to aqueous solutions by digestion procedures to minimize interferences and provide optimal precision and accuracy.

The most common atom cells employed for AAS are flames and electrothermal atomizers (ETAs). Flames, which employ a carefully controlled combustion environment to produce atoms, have the advantages of speed, ease of use, and continuous operation, which allows simple interface with chromatographic systems for speciation. However, the efficiency of sample introduction is typically 5%, and the atoms are dispersed across a relatively large volume, causing the sensitivity of flame AAS to be relatively poor (typically parts per million level). ETAs, also called graphite furnaces, employ a small graphite tube whose temperature can be accurately controlled by a power supply (**Figure 1**). Argon gas flows around the tube to prevent its combustion at elevated temperatures. Each ETA-AAS measurement involves a process called the 'atomization cycle'. ETA-AAS provides much higher sensitivity (typically parts per billion level, or picograms on a mass basis) compared to flame AAS because the atoms are concentrated in a relatively small volume and its high-(essentially 100%) atomization efficiency. In addition, ETA-AAS is capable of analyzing small volumes (typically 20  $\mu$ l per measurement).

However, the practical use of ETA-AAS for real sample analysis may be hampered by interferences, induced by nonanalyte components of sample (the sample matrix), that induce a change, either positive

**Figure 1** Schematic diagram of an electrothermal atomizer.

or negative, in the analyte absorption and prevent accurate analysis. Interferences are a much greater problem in ETA-AAS than flame AAS, and hence this article will focus on the former. A considerable amount of scientific effort was focused in the 1980s and 1990s to create instrumental developments and analytical protocols, called 'modern furnace technology' (MFT), to eliminate or at least minimize ETA-AAS interferences.

This article outlines the major types of interferences that are of significance in ETA-AAS, and the major components of MFT are outlined to describe ways to prevent interferences. Finally, an outline of procedures to develop methods for practical ETA-AAS analysis is provided.

## Types of Interferences for ETA-AAS

The three major types of interferences encountered in ETA-AAS are listed in Table 1. These include spectral, chemical, and physical differences in analytical standards and samples that may lead to inaccurate analysis by ETA-AAS. Detailed descriptions of these interferences are given below.

### Spectral Interferences

Spectral interferences involve a change in the amount of light that reaches the detection system by concomitants in samples. They can be classified as spectral overlaps, scatter, and molecular absorption.

Spectral overlaps arise in the relatively rare case in which a nonanalyte element absorbs light from the HCL. These interferences are relatively uncommon because the emission profile of an HCL is considerably

narrower than the absorption profile of the atoms in the ETA, and the interferent must be present at high concentrations. The most significant analytical spectral overlap occurs between gallium and manganese at 403.3 nm.

Scatter of source light occurs if particles are formed in the graphite tube that attenuates the source radiation. Particles may be formed from inorganic salts (e.g., sodium chloride), decomposition of organic compounds, or from the graphite tube at very high temperatures. The magnitude of the scattering coefficient  $\tau$  is given by Rayleigh's law of scattering:

$$\tau = 24\pi^3 \frac{N\nu^2}{\lambda^4} \quad [1]$$

where  $\nu$  is the volume of the scatterers ( $\text{cm}^3$ ).  $N$  is the density of scatterers (number  $\text{cm}^{-3}$ ), and  $\lambda$  is the wavelength of light (cm). This relationship shows that scatter has a maximum value in the presence of large scattering particles and at low-source wavelengths. Scatter may be a significant source of error for ETA-AAS. However, it is characterized by relatively constant magnitude as a function of wavelength, and hence its effects can usually be removed by the use of MFT.

Molecular absorption involves the absorption of HCL radiation by small molecules produced by components of the sample matrix. Alkali metal halide compounds absorb radiation throughout the ultraviolet region where most ETA-AAS measurements are performed, as shown in Figure 2. These broad spectra are caused by absorption of source emission that induces photodissociation of the molecules. In addition to photodissociation continuum spectra, other molecules are characterized by electronic band spectra, which are typically 0.5–10 nm in width and may be further split into vibrational and rotational

**Table 1** Types of interferences in ETA-AAS

Interference	Subclassification	Description
Spectral	Spectral overlaps	Absorption by nonanalyte atoms
	Scatter	Source light attenuated by particles
	Molecular absorption	Small molecules from sample matrix absorb light
Chemical	Volatile compound formation	Vaporization of analyte before atomization step
	Involatile compound formation	Incomplete vaporization of analyte during atomization step
	Gas-phase interferences	Gas chemical reactions between analyte and matrix components during atomization step
Physical		Differences in viscosity and surface tension of standards and samples

**Figure 2** Molecular spectrum of sodium chloride (5  $\mu\text{g}$ ) in an electrothermal atomizer. (Data from Culver BR and Surles T (1975) *Analytical Chemistry* 47: 920.

lines. Electronic band spectra are particularly difficult to correct for because of the variation in intensity across the absorption profile of the analyte.

### Chemical Interferences

Chemical interferences involve a chemical reaction between the analyte and components of the sample matrix that reduces the formation of gaseous atoms during the atomization step. These interferences may be further characterized based on the type of chemical reaction involved. Volatile compound formation involves a reaction between the analyte and a matrix component that produces a volatile molecule that is vaporized out of the furnace during the pyrolysis step. Involatile compound formation involves a reaction between the analyte and a matrix component that produces a molecule that is insufficiently volatile or sufficiently stable to reduce the formation of atoms during the atomization step. Gas-phase interferences refer to a chemical reaction between the analyte and a concomitant in the vapor phase.

Chemical interferences can be eliminated in most cases by the use of MFT (see below). Perhaps the most widely studied interference is the chloride interference for volatile elements such as lead and thallium, which causes vaporization of these elements at low temperatures (500°C). Although the mechanism of this interference has been widely studied, controversy still exists about its exact cause. Chemical interferences are also problematic for involatile elements. For example, metals that form involatile carbides, such as silicon, tantalum, and tungsten, are very difficult to determine by ETA-AAS because of their reactivity with the graphite tube.

### Physical Interferences

Physical interferences involve differences between physical properties of standard and sample solutions,

such as viscosity and surface tension, which result in changes in the ETA-AAS analytical signal. These differences typically do not affect the quantity of material introduced into the graphite tube, but may affect the degree of spreading of the sample on the tube surface. Increased spreading may increase analyte-graphite interactions and decrease the atomization efficiency of the analyte. As an example, physical interferences may be encountered using a sample introduction technique called slurry sampling, in which an aqueous slurry of a powdered sample is directly introduced into the tube. Surfactants are commonly added to these samples to assist in wetting and dispersing biological powders. However, these chemicals also increase spreading on the graphite and potentially induce a physical interference. These interferences may also be eliminated by the use of MFT.

## Modern Furnace Technology for Practical Analysis by ETA-AAS

The components of MFT for ETA-AAS are outlined in Table 2. These include instrumental developments, the use of high-quality graphite materials, a modern method of background correction, and chemical modifiers. The combination of these instrumental developments and protocols allows the routine use of ETA-AAS for real sample analysis.

### Instrumental Developments for ETA-AAS

In flame AAS, the sample is continuously introduced into the atom cell, producing a steady-state signal. Consequently, flame AAS instrumentation is designed to measure the peak height of this continuous signal, and this practice employed into early instrumentation for ETA-AAS. As described above, a discrete volume of sample (typically 20  $\mu$ l) is

**Table 2** Instrumental developments and analytical protocols involved in MFT

<i>MFT category</i>	<i>MFT component</i>	<i>Advantage</i>
Instrumental developments	Integrated absorbance	Better accuracy and precision than peak absorbance
	Fast electronics	Accurate characterization of transient signal
	Autosampler	Improved precision compared to manual pipetting
High-quality graphite	Pyrolytically coated graphite tubes	Reduced analyte-graphite reactions
	Transversely heated tubes	Reduced chemical interferences by vaporization into a uniformly hot tube
	Platform atomization with high-atomization heating rates	Atomization into a hot environment that reduces chemical interferences
Background correction	Zeeman effect	More accurate characterization of spectral interferences
Chemical modifiers		Reduced spectral and chemical interferences

**Figure 3** Electrothermal atomizer signal from a single furnace firing.

introduced into the graphite tube that is converted into gaseous atoms during the atomization step, resulting in a transient signal, as illustrated in **Figure 3**. The use of integrated absorbance, rather than peak absorbance, has been shown to provide superior accuracy and precision compared to peak absorbance. This is particularly true for real sample analysis, where the sample matrix may reduce the height of the analytical signal, but not its area.

The electronics for instrumentation designed flame AAS typically have long time constants (0.1–1 s) to smooth the steady-state signals obtained in this technique. However, the use of these electronics in early ETA-AAS instrumentation caused distortions of the transient ETA-AAS signals, which are typically a few seconds in width. Modern instrumentation for ETA-AAS employs time constants on the orders of milliseconds to prevent these errors.

Although autosamplers for flame AAS allow automated collection of data, they do not typically improve the accuracy and precision of analysis. Consequently, much of the early ETA-AAS literature employed manual pipetting. However, it is very difficult to reproducibly manually inject the small volumes employed in this technique. An autosampler should therefore be used to obtain the best accuracy and precision.

### Graphite for ETA-AAS

The types of graphite substrates may significantly affect the analytical performance of ETA-AAS (**Figure 3**). Early commercial instrumentation in the 1970s employed relatively large graphite tubes (50 mm in length by 8 mm diameter) composed of polycrystalline graphite. Although these tubes

accommodated large sample volumes, they were highly susceptible to chemical interferences that can be minimized by the methodology described below.

First, modern instrumentation uses smaller tubes (20–30 mm in length by 3–6 mm in diameter) that can be rapidly heated at more than  $1000^{\circ}\text{C s}^{-1}$ . High-heating rates allow the analyte to be rapidly atomized, improving precision. Second, chemical interferences between graphite and analytes were shown to be minimized by the addition of a 50  $\mu\text{m}$  layer of pyrolytic graphite on the surface of the tube, forming pyrolytically coated graphite. Pyrolytic graphite has a relatively high density and serves to reduce the chemical reactivity of the graphite. Pyrolytically coated graphite should always be employed for the determination of elements that may form carbides (e.g., vanadium, titanium, molybdenum). It is also effective at minimizing physical interferences due to increased analyte-graphite interactions.

Another approach to minimize interferences for volatile elements (e.g., lead, thallium) involves atomization into a tube that is at a relatively high temperature. Early work involved sample introduction directly onto the wall of the graphite tube. Under these circumstances, atomization occurred while the tube was still heating to the atomization temperature, which may allow gas-phase reactions to occur between the analyte and components of the sample matrix. In order to alleviate this problem, a small graphite shelf, called an 'L'vov platform', is inserted in the bottom of the graphite tube. Sample is introduced on to the platform. Since electrical current does not pass through the platform, it is heated radiatively by the tube walls, and hence its temperature is lower than that of the walls. This ensures that atomization occurs after the tube and gas inside it has reached a relatively high and constant temperature, minimizing chemical interferences.

Most furnace designs involve the passage of current through the length of the furnace using a longitudinal heating. This furnace design may cause severe temperature gradients, reported to be as large as  $1200^{\circ}\text{C}$ , between the center of the tube and its ends. These relatively cool regions may allow the analyte to condense or react with matrix components, resulting in interferences. An alternative to longitudinal heating is 'transverse heating', where the flow of current is perpendicular to the length of the tube (**Figure 4**). In this approach, the electrode contacts and L'vov platform are integrated as part of the graphite tube. This design has been shown to reduce interferences compared to longitudinal heating schemes.

**Figure 4** Transversely heated graphite tube with integrated platform and contacts.

### Background Correction for ETA-AAS

Spectral interferences may have a deleterious effect on the precision and accuracy of practical analysis performed by ETA-AAS. The effects of spectral backgrounds may be minimized by the use of methods of background correction. The basic goal of any method of background correction is the accurate measurement of the background absorbance, so it can be subtracted from the uncorrected signal (signal plus background) to give a background corrected signal. The ideal method of background correction would offer ease of use, low cost, applicability to all elements and wavelengths, measurement of background at the analytical wavelength, the use of one source, minimal effect on the detection limit or linear dynamic range, compatibility with a high-sampling frequency ( $>60$  Hz), and widespread use involving a variety of sample applications. As one might expect, no one method meets all of these criteria, and hence compromises must be made on some of these analytical parameters. In this article, the two most widely used methods of background correction are discussed: continuum source and Zeeman.

**Continuum source background correction** Continuum source background correction involves the use of a continuum source, such as a deuterium arc in the ultraviolet, or a tungsten halide lamp in the visible, to measure background attenuation. The spectral output from a HCL and the continuum source are alternatively transmitted through the graphite tube. The HCL has a narrow band emission profile (typically  $0.003$  nm) that may be attenuated by the analyte and molecules or particles responsible for the background signal. The continuum source has a relatively wide emission profile (typically  $0.2$ – $1$  nm), which is defined by the spectral bandpass of the monochromator, and may be absorbed by the sources

**Figure 5** Determination of arsenic ( $193.7$  nm) in the presence of  $\text{CaHPO}_4$  with continuum source background correction and a  $1$  nm spectral bandpass.

of background but not by the analyte. Therefore, electronic subtraction of the HCL measurement (signal plus background) minus the continuum source measurement (background) gives a background corrected measurement.

Continuum source background correction has two major limitations for practical analysis. First, it is difficult to exactly align the two light sources, which leads to inaccurate analyses, particularly at high-background levels. Second, it is unable to correct for background signals whose magnitude varies across the bandpass of the monochromator, which are called 'structured backgrounds'. Under these circumstances, continuum source background correction cannot provide accurate analyses. An example of a continuum source background correction error is shown in **Figure 5**, in which the measured background at the analytical wavelength is higher than the signal, resulting in a negative signal called an 'overcorrection error'.

In spite of these limitations, continuum source background correction may be used with good accuracy for many analyses. It offers low cost, wide applicability, operation at high frequencies, and little degradation in detection limits or linear dynamic range. It is commonly found in commercial instrumentation alone or with other methods of correction.

**Zeeman effect background correction** Zeeman effect background correction involves the use of the Zeeman effect, which involves the splitting of atomic lines into two or more components in the presence of an intense magnetic field (**Figure 6**). In general, these components only absorb one direction of polarized light, and hence the combination of a magnetic field and a polarizer may be used to make the background

**Figure 6** Normal Zeeman splitting pattern in a transverse magnetic field.

measurement. It is assumed that the background signals are not affected by the magnetic field, which is usually (but not always) a correct assumption. The most common arrangement for Zeeman ETA-AAS uses an electromagnet arranged around the graphite tube. Measurement when the magnetic field is zero gives signal plus background, measurement at the maximum field strength gives the background, and, hence, subtraction of the two gives a background corrected measurement. A number of instrumental configurations are commercially available for Zeeman ETA-AAS. These are beyond the scope of this article; readers are referred to the section Further Reading.

Zeeman effect background correction is generally regarded as the most accurate method, and it can be employed with almost all elements and transitions. However, it requires an expensive magnet system and typically degrades the analytical signal and linear dynamic range. In addition, a few reports have demonstrated interferences due to a molecule or second element with an absorption line very close to the analytical wavelength. Ideally, if cost is not an option, it may be preferable to be able to utilize both methods of correction, in case interferences limit the use of one of these methods.

### Chemical Modifiers for ETA-AAS

A very important facet of modern furnace technology involves the addition of chemical reagents, to standards and samples, to minimize interferences. These reagents are called chemical (matrix) modifiers. Modifiers serve to separate the analyte from the sample matrix to reduce spectral and chemical interferences. For volatile elements, such as lead, modifiers typically reduce the volatility of the analyte, allowing the use of a higher pyrolysis temperature that may allow removal of concomitants before the analytical measurement during the atomization step.

An ideal modifier would be available in high purity, minimize interferences, cause no reduction in the lifetime of the graphite tube, not be commonly

**Table 3** Chemical modifiers used for ETA-AAS

<i>Element</i>	<i>Recommended chemical modifiers</i>
Arsenic	Palladium nitrate and magnesium nitrate; nickel nitrate
Bismuth	Palladium nitrate and magnesium nitrate; nickel nitrate
Cadmium	Palladium nitrate and magnesium nitrate; diammonium hydrogen phosphate and magnesium nitrate
Chromium	Magnesium nitrate
Copper	Palladium nitrate and magnesium nitrate
Lead	Palladium nitrate and magnesium nitrate; diammonium hydrogen phosphate and magnesium nitrate
Manganese	Magnesium nitrate
Selenium	Palladium nitrate and magnesium nitrate; nickel nitrate and magnesium nitrate
Thallium	Palladium nitrate and magnesium nitrate; diammonium hydrogen phosphate
Zinc	Nickel nitrate

determined by ETA-AAS, and be applicable to many elements. A summary of commonly used modifiers is provided in Table 3. Commonly used modifiers include palladium nitrate, magnesium nitrate, diammonium hydrogen phosphate, and nickel nitrate. Palladium nitrate, either alone or with other compounds, best meets these criteria and is the most widely used modifier at this time. The introduction of oxygen as a modifier during the pyrolysis step, which is called oxygen ashing, has been used for the analysis of biological samples. Oxygen ashing has been shown to reduce formation of carbonaceous residue produced by these samples and minimize interferences.

## Flame

**S J Hill**, University of Plymouth, Plymouth, UK

### Introduction

Flame atomic absorption was until recently the most widely used techniques for trace metal analysis, reflecting its ease of use and relative freedom from interferences. Although now superseded in many laboratories by inductively coupled plasma atomic emission spectrometry and inductively coupled plasma mass spectrometry, flame atomic absorption spectrometry still is a very valid option for many applications. The sample, usually in solution, is sprayed into the flame following the generation of an aerosol by means of a nebulizer. The theory of atomic absorption spectrometry (AAS) and details of the basic instrumentation required are described in a previous article. This article briefly reviews the nature of the flames employed in AAS, the specific requirements of the instrumentation for use with flame AAS, and the atomization processes that take place within the flame. An overview is given of possible interferences and various modifications that may provide some practical advantage over conventional flame cells. Finally, a number of application notes for common matrices are given.

### Types of Flame

In AAS, the flame is only required to produce ground state atoms. Two types of flame are employed to achieve this: the premixed combustion flame consisting of a fuel and oxidant gas, and the diffusion flame where the fuel is also the carrier gas that burns on contact with air. Premixed flames commonly employ either air or dinitrogen oxide as the oxidant, and either acetylene, propane, or hydrogen as the fuel gas.

The temperature of diffusion flames is lower than that of premixed flames, although it must be remembered that atomization occurs as a result of both the high enthalpy and temperature of the flame and through chemical effects (i.e., chemical compounds and radicals within the flame), as discussed below. Thus, although the burning temperatures of two different premixed gas flames may be similar, the analytical characteristics can be very different. The characteristics (indicative values) of some commonly used flames are shown in **Table 1**.

Of the various flame types available, the air–acetylene flame is the most widely used. This flame is stable, simple to operate, and produces sufficient atomization to enable good sensitivity and freedom from many interelement interferences. Over 30 elements may be determined using an air–acetylene flame, although the flame conditions may have to be adjusted to create a suitable environment for some elements. For example, the alkaline earth metals require a fuel rich (reducing flame), whilst the noble metals are determined using a lean (oxidizing) flame. In many cases, however, increasing the oxygen content of the flame may be counterproductive since although this will produce a hotter flame it may also promote the formation of refractory oxides. Ionization will occur in an air–acetylene flame for a number of easily ionized elements such as the alkali metals. In such cases, an ionization suppressor or buffer consisting of a large excess of an easily ionized element (such as cesium or potassium) may be added. This has the effect of suppressing the ionization (e.g., sodium) by a simple mass action effect resulting from the excess cesium in the flame. The alkali metals may be determined using an air–propane flame, although such flames are seldom used these days, atomic emission spectrometry being the preferred technique for such elements.

**Table 1** Typical characteristics of premixed flames used in AAS

Flame type	Flow rates ( $\text{l min}^{-1}$ )		Approximate temperature (K)	Maximum burning velocity ( $\text{cm s}^{-1}$ )
	Fuel	Oxidant		
<i>Air-propane</i>				
Lean	0.3	8	2200	45
Stoichiometric	0.3–0.45	8		
Rich	0.45	8		
<i>Air-acetylene</i>				
Lean	1.2	8		
Stoichiometric	1.2–1.5	8	2450	160
Luminous	1.5–1.7	8		
Rich	1.7–2.2	8	2300	
<i>N<sub>2</sub>O-acetylene</i>				
Lean	3.5	10		
Stoichiometric	3.5–4.5	10	3200	285
Rich	4.5	10		
<i>Air-hydrogen</i>				
Stoichiometric	6	8	3200	320
<i>N<sub>2</sub>O-hydrogen</i>				
Stoichiometric	10	10	2900	380
<i>N<sub>2</sub>O-propane</i>				
Stoichiometric	4	10	2900	250

Another premixed flame commonly employed is the dinitrogen oxide (nitrous oxide)–acetylene flame. This flame is both hot and reducing and commonly used for the determination of elements such as Al, B, Ba, Be, Mo, Nb, Re, Sc, Si, Ta, V, W, Zr, the lanthanoids, and actinoids. This type of flame has a characteristic red inter-conal zone due to the presence of the cyanogen radical that is produced under slightly fuel-rich conditions. This radical is a very efficient scavenger of oxygen and the higher temperature aids in promoting dissociation. For safety reasons, the nitrous oxide–acetylene flame should never be run fuel-lean and carbon deposits should not be allowed to build up on the burner (a 5 cm slot burner is used). To establish the flame, an air–acetylene flame is lit first, made very fuel-rich, and then switched to nitrous oxide–acetylene using a two-way valve. The flame is shut down using the reverse procedure.

Hydrogen diffusion flames are used to determine easily atomized elements such as arsenic and selenium. Often such flames, for example, the argon–hydrogen flame, are used in conjunction with hydride generation techniques. The flame itself is transparent over a wide spectral range and so has some benefit over hydrocarbon flames that will absorb strongly at low wavelengths.

## Sample Introduction and Burner System

In order for the atom cell, i.e., the flame, to function effectively and produce an atomic vapor, the sample

must be presented in the form of a fine aerosol. This is achieved using a nebulizer and spray chamber prior to the burner. A typical pneumatic nebulizer system for a premixed flame is shown in **Figure 1**. The sample solution is sucked up a plastic capillary tube by the reduced pressure created at the end of the tube by the oxidant or carrier gas flow, i.e., the Venturi effect. During this process the sample is shattered into tiny droplets as it exits the capillary tube to produce an aerosol. This process may be optimized with respect to sample uptake and drop size by adjusting the position of the nebulizer capillary. Additionally, an impact bead may be placed in the path of the initial aerosol to provide secondary fragmentation. Both the nebulizer and impact bead must be made of corrosion-resistant material such as a platinum–iridium alloy (90:10) or stainless steel coated with an inert plastic.

Once formed, the aerosol passes into the burner or spray chamber (sometimes also called the cloud chamber). The role of the spray chamber is to homogenize both the aerosol and gases that tend to dampen fluctuations in nebulizer efficiency, and to remove any large droplets before they reach the flame. Large droplets (diameter  $> 10 \mu\text{m}$ ) collect on the sides of the chamber and then drain to waste. Spoilers and baffles placed at the end of the spray chamber aid this process. Because the spray chamber will fill with flammable gas, modern instruments will also incorporate some form of antiflashback protection from the flame.

**Figure 1** Diagram of nebulizer, spray chamber, and burner system components as used in the PerkinElmer AAnalyst 200/400 atomic absorption spectrometer. (Reproduced by kind permission of PerkinElmer Inc. All rights reserved.)

Although the nebulizer and spray chamber arrangement described allows only small droplets to reach the flame, the efficiency in terms of sample transport is only  $\sim 10\%$ . Ultrasonic nebulizers offering higher efficiency are available, but these are more complicated and have a tendency to suffer from memory effects, i.e., contamination from previous samples. Organic solvents also improve the efficiency, probably forming smaller droplets as a result of their lower surface tension. However, organic solvents may also affect nebulization because of their different density, viscosity, and saturated vapor pressure. In addition, they may also act as secondary fuels, thus affecting the flame.

The introduction of solid powder samples is possible using pneumatic sampling devices. Various graphite capsules and vibration tubes have also been used on this form of sample. In both cases the

precision is very poor and the introduction of powders is thus seldom attempted these days.

The design of the burner employed in AAS depends on the oxidant-fuel gas mixture. Slot burners are now used almost exclusively, the length of the slot being 10 cm for use with air-acetylene and multishot burners, and 5 cm for nitrous oxide-acetylene burners, reflecting the higher burning velocity of the flame as shown in Table 1. The slot width and the conductivity of the metal used for the construction of the burner are also important in terms of stability of operation and prevention of clogging. The burner should also be constructed or coated in an inert material to avoid corrosion.

### Atomization Processes in the Flame

Once the aerosol reaches the flame the droplets are desolvated to form a mist of salt clotlets, which

then fuses and evaporates or sublimates. This process is critically dependent on the size and number of the particles, their composition, and the flame mixture. As the absolute concentration of analyte in the flame is very small ( $<10^{-3}$  atm), the saturated vapor pressure may not be exceeded even at temperatures below the melting point. The vaporization is fast; the molecules that make up the vapor decomposing into individual atoms almost instantaneously. In fact, the distance that the sample travels through the flame before atomization may be very short, for example, less than 1 cm for sodium chloride in an air-acetylene flame. Higher in the flame the sodium concentration will slowly decrease due to cooling of the flame and the composition of the flame has little effect on the atomization process. Other species, however, are more refractory (e.g., the alkaline-earth and rare-earth oxides) and may require a hotter flame and reducing environment to aid dissociation, thus reflecting the importance of flame chemistry (both ground state and excited atoms may be produced by radical reactions in the primary reaction zone of the flame). Since dissociation and the subsequent ionization of a diatomic compound are similar processes, it is possible to calculate the degree of ionization of atoms into ions and electrons for different elements as a function of temperature and partial pressure using the Saha equation.

For many elements the atomization efficiency, defined as the ratio of the number of atoms to the total number of analyte species, atoms, ions, and molecules in the flame, is 1, although for other elements (e.g., the lanthanoids) it is less than 1, even in a nitrous oxide-acetylene flame. However, the formation of atoms is not the end of the story since once formed they may be lost through compound formation or ionization. Ionization increases exponentially with temperature and is a particular problem for the elements on the left of the periodic table, i.e., the alkali and the alkaline-earth elements. It is also a problem with Al, Ga, In, Sc, Ti, and Tl in the nitrous oxide-acetylene flame. A summary of atomization in flames is presented in Figure 2.

## Interferences and Errors

The use of a line source and the ratio method (i.e.,  $I^\circ/I$ ) tend to minimize errors in AAS, since many instrumental errors such as long-term source drift, small monochromator drifts, should be cancelled out. However, a stable uptake rate, or aspiration rate, is required. There are principally three types of interference that may be identified in flame AAS: chemical, ionization, and spectral interferences. Both

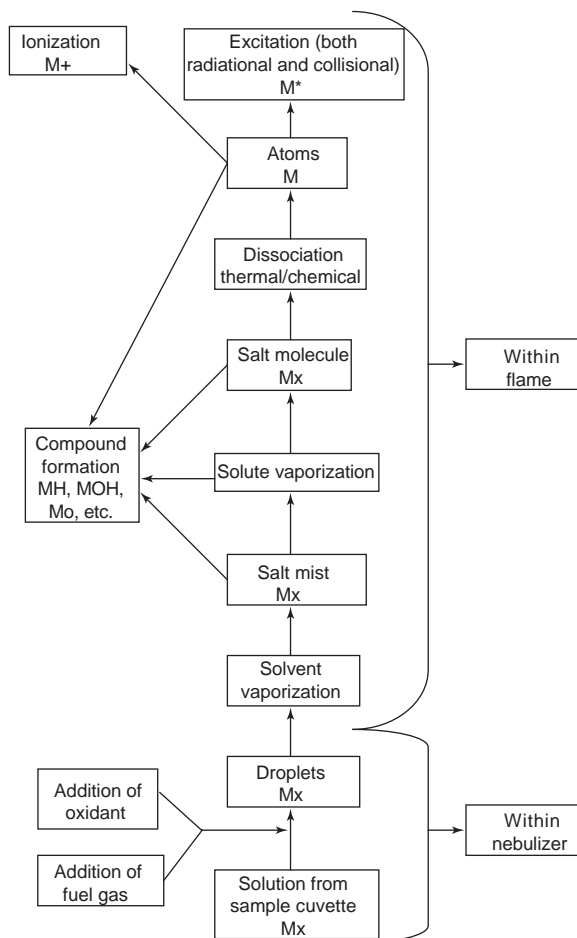

Figure 2 Summary of atomization in flames.

chemical and ionization interferences require the presence of an analyte.

## Chemical Interferences

Chemical effects may originate from either the sample solution or the flame and represent the major type of interference in flame-AAS. The mechanisms behind chemical interferences can be split into two types. The first of these is where the atomization of the analyte is not complete through occlusion into refractory compounds. Stable compound formation of this type will cause a depression of the signal through physical entrapment of small amounts of analyte in clots of matrix oxide in the flame. In premixed laminar flames the volatilization of solid particles begins as soon as they enter the primary reaction zone. The time this process takes is dependent on the size of the particle and so the occurrence of such interferences will depend critically on the observation height in the flame. In the second type, the analyte atoms may react with other atoms or

radicals, leading to the formation of less volatile (or, occasionally, more volatile) compounds. The best-known example of this type of interference is that of phosphate on calcium, although sulfate and silicate have similar effects. The interference manifests itself as a pronounced 'knee' in plots of increasing phosphate concentration against calcium signal. The constant level of interference following the 'knee' suggests formation of a compound that is less volatile than calcium chloride (probably calcium phosphate), which restricts the formation of calcium atoms. There are many other examples of this type of interference, all showing this pronounced 'knee', which distinguishes them from nonspecific occlusions. To overcome this type of interference it is possible to use a hotter flame (the interference of phosphate on calcium is not observed in a nitrous oxide–acetylene flame), make observations higher in the flame, use a 'releasing agent' (an excess of lanthanum or strontium releases calcium from phosphate interference), or finally to use a protective chelating agent (excess ethylenediaminetetraacetic acid (EDTA) protects calcium from the phosphate interference).

### **Ionization Interferences**

This is a vapor-phase interference that may be particularly troublesome for elements with low ionization potentials such as the alkali metals and some alkaline-earth metals when using an air–acetylene flame, and elements having an ionization energy of 7.5 eV or lower using a nitrous oxide–acetylene flame. In such cases, the analyte is partly ionized in the flame, leading to a decrease in the absorption signal. However, the extent of the ionization for a specific element and temperature is dependent on the concentration element. For example, the ionization of barium is strongest at low concentrations and results in curvature of the analytical curve precluding trace analysis. The effect can be explained in terms of the self-suppression of the ionization (see above).

Ionization interferences may be suppressed in two ways. First, a cooler flame may be employed, for example, the alkali metals are little ionized in the cooler air–hydrogen flame. However, this approach is not suitable for the majority of the elements since they are either not determined in cool flames (e.g., the lanthanoids) or subject to solute-volatilization interferences (e.g., barium). The second approach is to shift the ionization equilibrium on the basis of the law of mass action by producing a large excess of electrons in the flame or by charge transfer. In practice, this is simply achieved by adding a large excess of an easily ionized element (e.g., potassium) to both the sample and reference solutions. The effect of this

is to ionize the buffer element in the flame, whilst suppressing the ionization of the analyte.

### **Spectral Interferences**

Spectral interferences in AAS due to direct overlapping of the emission lines from the primary radiation source and the adsorption line of another element in the atom cell are very rare. To give rise to a spectral interference, the lines must not merely be within the band pass of the monochromator, but must actually overlap with each other's spectral profile (i.e., be within 0.01 nm). Spectral interferences resulting from the overlap of molecular bands and lines are more of a problem in AAS. Examples of this type of interference are the nonspecific absorption at 217.0 nm which affects lead (e.g., sodium chloride gives a strong molecular absorption at this wavelength), and the calcium hydroxide absorption band on barium at 553.55 nm. Spectral interferences may usually be eliminated by the use of background correction.

### **Modifications to Conventional Flame Cells**

The use of flame atom cells has many advantages for routine analytical determination. These include the fact that most elements can be readily atomized by the appropriate flame; flame cells are easily optimized and simple to use; and due to their long history much is known about their fundamental behavior. In addition, flames give a steady signal and offer signal-to-background and signal-to-noise ratios that facilitate good sensitivity and precision (0.4–2% r.s.d.) over a wide wavelength range (200–800 nm). However, there are also a number of practical disadvantages that may be encountered when using conventional flame cells. The first of these is that conventional indirect flame systems require relatively large volumes of solution to operate, reflecting the fact that only ~10% of solution uptake is delivered to the flame. Samples also have short transit times in the flames, giving rise to the possibility of incomplete vaporization as discussed above, and once the atoms are formed they are subject to dilution effects from the relatively high flow rate of unburnt gas used to support the flame. It has been estimated that atoms spend only  $10^{-4}$  s in the analysis volume – much less than is required to give a stable signal. Finally, although the sample introduction works well for aqueous solutions, difficulties may be encountered when trying to nebulize organic solvents (which may extinguish the flame) or introduce solids. To overcome these shortfalls, a number of modifications to the flame cell have been proposed.

Small samples ( $25\text{--}200\text{ mm}^3$ ) may be introduced using the technique of pulse nebulization (also known as discrete sample nebulization, direct-injection cup nebulization, gulp sampling, and Hoescht cup nebulization). This technique may also be employed for higher concentrations than normally nebulized. A cup or funnel made of an inert material (e.g., polytetrafluoroethylene) is attached to the nebulizer tubing and the sample is put into the cup as a discrete aliquot using a micropipette. The sample is totally consumed and the transient peak signal recorded.

The use of branched uptake capillaries, connected to the nebulizer using a T-piece, may be advantageous when a buffer or ionization suppressor is required. In addition to avoiding time-consuming solution preparation, it is also possible to calibrate organic extracts using aqueous standards in this way. The approach may also be extended to couple more complex flow injection systems employing novel chemistries in the same way.

The final modification commonly employed is the use of sampling boats and cups. One of the first examples of such a device was the Kahn sampling boat, where the sample was evaporated from a tantalum boat that was simply pushed into the flame. An improvement in sensitivity may be achieved for the more easily atomized elements, although the reproducibility is often poor. A modification to this approach was later (1970) reported by Delves, who replaced the tantalum boat with a nickel microcrucible, the so-called Delves cup. The cup itself is mounted onto a device that allows it to be positioned near the flame to char the sample before insertion into the flame to allow atomization. A nickel absorption tube was also positioned in the flame (aligned with the hollow cathode lamp in such a way as to allow the light to pass through the tube unhindered), the atoms entering through a hole half-way along its length. In this way the residence time of the atoms in the flame could be increased. Such devices are now seldom used.

The use of tubes to increase the residence time of atoms in the analytical zone, and hence improve detection limits have more recently been reported for a variety of applications. Such tubes are often fabricated from silica and employ slots, one directly above the burner slot and the other usually at  $180^\circ$ , to decrease the turbulence of the hot gases. The improvement in sensitivity associated with these tubes is generally confined to those elements readily dissociated to their ground state atoms in the flame. Elements with relatively high metal-oxide dissociation energies such as some of the transition metals that

are normally best determined using the nitrous oxide–acetylene flame are precluded because of the excessive thermal shock this hotter flame would impose on the quartz tube.

Although very useful for many applications, it should be stressed that the above devices will not overcome all of the problems associated with the use of flames. For example, they will not help alleviate the banded and continuous spectra that give rise to background radiation in flames. The banded spectra arise from the excited molecules and radicals in the flame gases, whilst the dissociation, ionization, and recombination of these species give rise to the continuous spectra. Such background radiation is a particular problem with flames when using low wavelengths (i.e., below  $200\text{ nm}$ ). Other problems associated with the use of flames include scatter radiation resulting from particulate matter in the light path, and various safety requirements, particularly with regard to explosion hazards (always present with flames of high burning velocity) and toxic flame products (necessitating the use of extraction systems).

## Selected Applications

There are many applications for flame atomic absorption spectroscopy, most requiring the sample to be in solution. Table 2 lists typical detection limits that may be obtained on a modern instrument, together with details of the flame type recommended for each element. In practice, the concentration of the analyte in solution should be at least 10 times greater than the detection limit.

### Liquid Samples

Information on total analyte levels in aqueous samples may be obtained directly following acidification of the sample, providing the analyte is present in sufficient concentration. Samples may also be filtered to provide information on the dissolved fraction, although losses may occur during the filtering process. Samples with analyte concentrations below the detection limits may be preconcentrated using either evaporation or ion exchange resins prior to analysis. Scale expansion may also be employed. On the other hand, if the analyte is in high concentration, the solution must be diluted to within the linear working range, or some other means of reducing the sensitivity employed such as removal of the impact bead, burner rotation, or the use of alternative less-sensitive absorption lines. Releasing agents and ionization buffers may be required for some samples, although these should be used in

concentrated form in order to avoid any undue dilution of the sample where trace elements are to be determined.

Nonaqueous solutions may also be nebulized directly providing the viscosity is similar to that of water for which most nebulizers are designed. Both white spirit and methyl isobutyl ketone fulfill this requirement and these may be used as diluents for other organic liquids. Standards may be prepared in the pure basic solvent.

### Soils and Sediments

Clearly some form of sample pretreatment is required for soils and sediments. Total levels may be obtained following sodium carbonate–boric acid fusion and the dissolution in hydrochloric acid employing lanthanum as a buffer and releasing agent. If the determination of silicon is not required, it may be volatilized as silicon tetrafluoride using hydrofluoric acid, although some calcium may also be lost as calcium fluoride. For many samples, however, it may be more appropriate to determine the exchangeable cation content of the sample. Here, the sample may be shaken with an extractant solution, for example,  $1 \text{ mol l}^{-1}$  ammonium chloride, ammonium acetate, or disodium EDTA, prior to filtration and analysis. Where final solutions contain more than  $\sim 0.5\%$  of dissolved material, the standards should also contain the major constituents, even where no chemical interference is expected, in order to match the viscosity and surface tension and avoid ‘matrix’ effects.

### Plant Material

Plant material should be dried at  $40^\circ\text{C}$ , crushed to pass through a  $0.5\text{--}0.7 \text{ mm}$  sieve, and then oven-dried at  $105^\circ\text{C}$ . The dried material must then undergo dissolution using a suitable digestion procedure such as treatment with hydrogen peroxide–sulfuric acid mixture, or sulfuric, perchloric, nitric acid mixtures. Care must always be taken to avoid the loss of volatile elements such as lead and cadmium during digestion. Contamination from reagents should also be avoided. It is also possible to extract a number of elements quantitatively from plant material and organic residues by boiling in hydrochloric acid. Both ashing and acid extraction methods may be used as a preliminary step to concentration by solvent extraction of elements that are normally too low in concentration to be measured directly in a flame.

### Introduction

Electrothermal (ET) atomizers, which were first used for analytical work by L'vov in the late 1950s, typically consist of a tube of electrically conducting material, usually manufactured from graphite (hence the

**Figure 1** End-heated (a) and side-heated (b) electrothermal atomizer configurations. A, water-cooled graphite electrical contact cylinders; B, graphite tube; C, sample injection port; D, light path of spectrometer.

name graphite furnace), mounted in the light path of a spectrometer (see **Figure 1**). Metals such as tungsten and tantalum are also used to construct ET atomizers, in particular for the determination of carbide-forming elements. After the sample to be analyzed has been introduced, via a small aperture in the upper tube wall, the atomizer is heated resistively through a series of controlled temperature stages. Nowadays computer-controlled programs regulate the starting and final temperature, the rate and timing of the graphite tube heating, and even the gas (Ar or N<sub>2</sub>) flush of the tube. During the initial steps in this procedure, the sample is dried and thermally pretreated (pyrolyzed), facilitating the selective volatilization of matrix components, which are purged from the atomizer by a flow of argon gas. The tube is then rapidly heated (1000–2000°C s<sup>-1</sup>) to a sufficiently high temperature (1000–2700°C) to atomize the element of interest, during which time the transient absorbance signal is recorded.

Because the material that is used to form the tube surface is practically impermeable to gas (pyrolytic graphite), the atomic vapor is contained in the atomizer for a relatively long time, normally for a few tenths of a second. This long residence time, together with the high degree of analyte atomization caused by the reducing environment, leads to a factor of  $\sim 10^3$  increase in sensitivity compared with flame atomic absorption spectrometry (AAS). In contrast to the latter, solutions, slurries, and solids can be conveniently analyzed and the possibility for *in situ* removal of matrix components significantly reduces the risk from interferences. The high optical transparency of the argon atmosphere in the ET atomizer favors light transmission, which is important for measurements in the wavelength region 190–230 nm.

## Atomizer Design and Temperature Characteristics

Equation [1] is a simplified expression for the dependence of the peak area or integrated absorbance signal,  $A_{\text{int}}(s)$ , on the atomizer geometry:

$$A_{\text{int}} = k(T, P) N \frac{\tau_R}{\sigma} = k(T, P) N \times \frac{l^2}{8D(T, P)} \times \frac{1}{\pi r^2} \quad [1]$$

where  $k$  (cm<sup>2</sup>) is the temperature ( $T$  (K))- and pressure ( $P$  (Pa))-dependent absorption coefficient,  $N$  is the total number of analyte atoms in the sample,  $\tau_R$  (s) is the mean residence time of analyte atoms in the absorption volume,  $\sigma$  (cm<sup>2</sup>) is the cross-sectional area of the ET atomizer, and  $l$  (cm) and  $r$  (cm) are the length and inner radius of the tube, respectively, and  $D$  (cm<sup>2</sup> s<sup>-1</sup>) is the diffusion coefficient or ‘interdiffusivity’ in terms of the Chapman–Enskog theory. This equation is valid if the concentration of atoms decreases linearly from the center to both ends of the tube, and assumes that all the analyte is converted to free atoms. Furthermore, the temperature (and pressure) in the atomizer should be constant to avoid changes in  $k$  and  $D$  during the development of the absorbance signal. The peak height shows a more complicated dependence on the atomizer heating rate and rate of atom formation, in addition to the factors included in eqn [1].

For optimum sensitivity, the tube should be as long as possible and have a rather small diameter. However, practical considerations dictate that the tube radius should be large enough to transmit a sufficiently high-radiation flux and to introduce large sample volumes or masses. Limitation on the tube length is placed by the need to provide high heating rates at reasonable power consumptions. Thus, the

tube dimensions must constitute a workable compromise between the aforementioned aspects and high sensitivity.

The most important feature of ET atomizers is their heating characteristics. In ET-AAS they determine factors such as the magnitude of interferences, background absorbance, and memory effects, as well as sensitivity. Thus, a clear understanding of the temperature development in various atomizers is a prerequisite to understanding atomizer possibilities and limitations.

Figure 2a shows the change of the wall temperature with time of an end-heated atomizer at the center and two off-center positions. During the initial heating phase the atomizer is isothermal over a substantial tube length (i.e., spatially isothermal) but a temperature gradient develops with time because of heat losses to the water-cooled contacts. It should be mentioned that the onset of this gradient will be shifted toward earlier times if tube heating commences from a higher temperature, i.e., when a thermal pretreatment step immediately precedes atomization, or when a more efficient water cooling is used. Here, the temperature at which atomization/vaporization from the wall takes place cannot be controlled. Depending on its physical properties, the sample normally starts to vaporize at relatively low temperatures often insufficient for complete atomization. The fact that the temperature of the tube may be rising during measurements (i.e., the tube is temporally nonisothermal) introduces various problems, in particular, when the integration method of peak evaluation is used since both the absorption

coefficient and atomic residence time in the atomizer are temperature dependent, as seen in eqn [1]. Elements of low volatility that are vaporized at the relatively high temperatures associated with thermal gradient development may either condense or adsorb on cooler wall regions located away from the tube center. Revaporization may follow during a subsequent atomization sequence (memory effects), since these regions will then initially attain a higher temperature. For the high heating rates used, and in the absence of convection, the atomizer gas-phase temperature closely follows the wall temperature for each cross-section of the tube.

As can be seen in Figure 2b, the side-heated atomizer provides spatial isothermality, which substantially reduces condensation and memory effects.

To overcome problems with analyte vaporization during tube heating, L'vov proposed introducing the sample onto a small platform of graphite (see Figure 3). The heating characteristics of platform-equipped tubes are only slightly different from those without a platform. However, since the platform has a finite heat capacity and is heated primarily by tube radiation, the platform temperature will lag significantly behind that of the tube wall. The sample will therefore be volatilized later in time (relative to wall atomization), and at higher tube and gas-phase temperatures, which normally favor atom formation. Thus, the platform simply reduces interference effects arising from temporal nonisothermality.

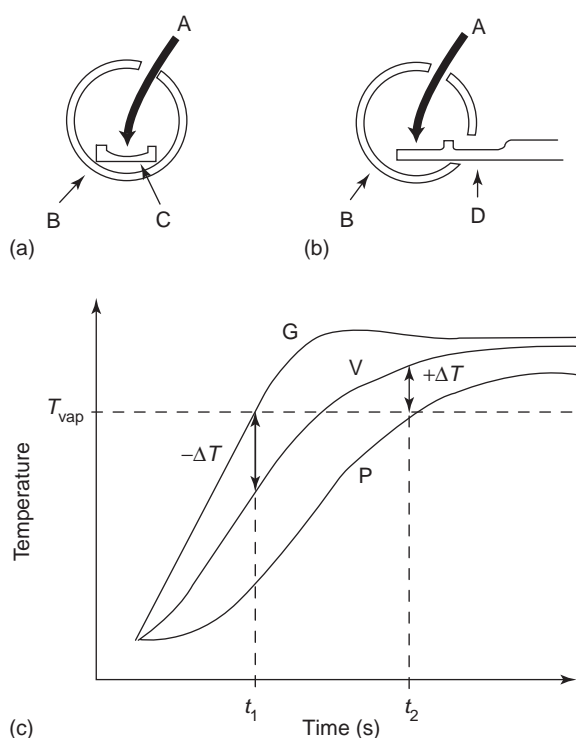

An alternative way to achieve atomization under temporally isothermal conditions is to place the sample on a graphite probe (see Figure 3). The probe is removed from the tube prior to the atomization stage, and then reintroduced once the tube has reached the set temperature. This system is more complex than the platform, and requires the presence of an additional aperture in the tube, which reduces sensitivity. The use of platforms and probes is very efficient in reducing interference effects, but suffers from the disadvantage that the processes of vaporization and atomization are coupled, which may sometimes require compromise conditions.

The temperature characteristics of a constant temperature two-step atomizer are shown in Figure 4. The main advantage of such constant temperature atomizers is their ability to introduce the sample into the measuring zone at any selected temperature and at variable heating rates up to at least  $3000^{\circ}\text{C s}^{-1}$ . This allows selective volatilization of the analyte separately from the matrix, or very slow vaporization of the sample to keep the peak absorbance signal within the linear range.

The description of temperature characteristics in atomizers is further complicated by the fact that the

**Figure 2** Temperature distribution as a function of time in the end-heated (a) and side-heated (b) atomizers shown in Figure 1. The graphite tubes are 28 and 17.5 mm long in (a) and (b), respectively, and  $z$  is the distance from the tube center (mm) where the temperature measurements were made.

**Figure 3** Schematic illustration of platform (a) and probe (b) atomization for ET-AAS. The sample is injected (A) through the injection port in the graphite tube (B) onto the platform (C) or probe (D). In (c), the heating profiles for the graphite tube wall (G), the vapor phase (V), and the platform (P) are shown. For atomization from the wall, the analyte vaporizes ( $T_{\text{vap}}$ ) at a time point ( $t_1$ ) when the vapor phase is at a much lower temperature than the graphite tube ( $-\Delta T$ ). Volatilization from the platform commences after a substantial time delay ( $t_2$ ) when the temperature of the vapor phase is higher ( $+\Delta T$ ) than that of the platform ( $T_{\text{vap}}$ ). Furthermore, the vapor-phase temperature is almost constant (temporally isothermal), a prerequisite for the use of peak area signal evaluation, as discussed in connection with eqn [1]. The higher vapor-phase temperature obtained using volatilization from the platform rather than from the wall favors dissociation or atomization of analyte species. Using the probe, the delay time for sample introduction into the vapor phase can be more exactly controlled.

platform or sample compartment is, by design, at a lower temperature than the tube wall during the initial stages of the atomization step. The resulting thermal gradient between the point where the sample is deposited and the tube wall decreases with time. Although this radial temperature gradient is not as pronounced as that along the axis in end-heated furnaces, spatially resolved measurements have indicated that interferences are greater in the immediate vicinity of the platform than at the opposite tube wall. Strictly speaking, none of the atomizers discussed is completely void of temperature gradients, but they differ greatly in the degree of nonisothermality. Toward isothermal atomization the transversely heated graphite atomizer (HGA) has definitely been a

**Figure 4** Schematic illustration of a constant temperature two-step atomizer (a). The sample is injected (A) through the injection port in the side-heated graphite tube (B) and deposited in the sample cup (C). Heating of the tube (at D) and the cup (at E) is achieved by means of two power supplies connected at the water-cooled contact points (D, E). Heating profiles for the tube (F) and cup (G, H) are shown in (b). By reducing the cup heating rate, the rate of sample introduction into the measurement zone (graphite tube) can be controlled to allow large sample masses to be volatilized without exceeding the linear response range. Traces (I) and (J) show the effect of high (G) and low (H) heating rates, respectively, on the signal shape.

major step. The most pronounced advantages in comparison with the longitudinally HGA are the isothermal wall temperature and the very small temperature gradient in the gas phase along the tube axis that can be further reduced by using end-capped tubes.

Integrated platform is an efficient tool to achieve isothermal atomization with respect to time. The platform acts as a thermal ballast with reducing the temporal heating rate during the applied rapid heating and thus creating radial temperature gradients between platform and tube wall. While temperature gradients are always in the direction toward hotter temperatures, therefore beneficial with respect to efficient atomization and the reduction of gas-phase interference, they cannot be ignored regarding their effect on detection. As long as there are temperature gradients, the atomic absorption signal of atoms released from the platform will depend on their location inside the atomizer volume, i.e., on their distance above the platform.

## Mechanisms of Atomization

The understanding of mechanisms leading to atom formation in ET-AAS is still superficial and, to some extent speculative, because of the complex dynamic system under consideration. It should be emphasized that it is difficult to characterize condensed and gaseous phase species in systems where fast reactions of small masses (picograms to nanograms) of analyte are studied in a high-temperature environment.

### Characterization of the Condensed Phase

Since graphite tubes are used almost exclusively in ET-AAS, the following discussion will be confined to this substrate. The base material in graphite tubes for ET-AAS, polycrystalline electrographite, is composed of a large number of disordered crystals, irregularly aggregated to form macroscopic grains, which are held together by carbon binder bridges. This material has anisotropic properties and fulfills the analytical requirements of being resistant to thermal shock and having the appropriate electrical conductivity. The surface is coated with a layer ( $\sim 50\ \mu\text{m}$ ) of high-density pyrolytic graphite, vapor-deposited under carefully controlled conditions of temperature, pressure, and type of hydrocarbon gas. As well as having a low permeability to gases, the pyrolytic graphite coating is relatively resistant toward oxidation due to the high degree of crystalline order. Nevertheless, different types of active sites are present, particularly at the edges of the basal graphite planes, where gases may be adsorbed (analyte,  $\text{H}_2\text{O}$ ,  $\text{CO}_2$ ,  $\text{CO}$ ,  $\text{O}_2$ ,  $\text{H}_2$ ). Some of these species may react with the carbon atoms at active sites, the reaction products being released at various temperatures during heating, depending on the nature of the initial reactants. For example, the reaction between carbon and molecular oxygen proceeds rapidly at temperatures above 1200 K and is kinetically controlled by the reactivity of the surface below 2000 K. Loss of carbon atoms from the lattice creates new active sites, and so the presence of oxidants may change the surface properties.

Oxygen has nevertheless been used successfully during thermal pretreatment of biological sample matrices to both facilitate decomposition of organic material and stabilize the analyte (aluminum, cadmium, lead, selenium) in oxide format active sites. However, the pretreatment temperature must be accurately controlled to prevent oxidation of graphite.

The analyte can be distributed in different ways on the surface of the graphite (tube wall, platform, or probe) as a monolayer, spheres, crystal caps, intercalated between the pyrolytic graphite layers, or adsorbed on active sites. The physical form of the analyte, as well as its chemical properties, helps to

decide the order of atom release as well as the activation energy of the atomization process.

### Characterization of the Gaseous Phase

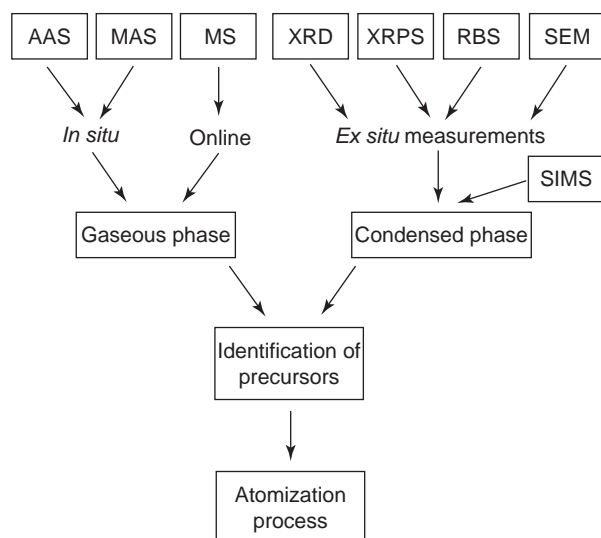

The gaseous phase in an ET atomizer, unlike that in a flame, has a very low-buffer capacity and thus can be influenced dramatically by sample constituents. The chemical composition changes rapidly with temperature and time, depending on the sample matrix, graphite surface properties, thermal pretreatment temperature, impurities in the inert purge gas, and ingress of air through the injection port. For example, in an argon atmosphere of 2000 K, using the type of atomizer shown in **Figure 1a** and without sample addition, the partial pressure of carbon monoxide,  $p(\text{CO})$ , is  $\sim 10^2\ \text{Pa}$ , and at 3000 K  $p(\text{C}_2)$  and  $p(\text{CN})$  are  $\sim 4$  and  $0.6\ \text{Pa}$ , respectively, the latter figure referring to a nitrogen atmosphere in the atomizer. During atomization of a sample pretreated at a high temperature, the partial pressures of carbon monoxide and other oxidant species (such as  $\text{O}_2$ ,  $\text{NO}$ ,  $\text{NO}_2$ , and  $\text{HNO}_3$  from nitrate decomposition) are often increased, while  $p(\text{CN})$  is reduced. This means that oxidants generated during sample matrix decomposition can evolve into the gas phase without complete reduction by the graphite at temperatures below 2000 K.

### Analytical Techniques for the Investigation of Atomization Mechanisms

To establish the processes leading to atom formation it is essential to monitor and identify, *in situ*, the precursors to free atoms in the condensed and gaseous phases. As can be seen from **Figure 5**, no single analytical technique fulfills this requirement.

There is as yet no readily available technique capable of *in situ* registration of analyte species on the atomizer surface during heating. Furthermore, most of the techniques available are not sensitive enough for measurements using typical analytical masses (picograms to nanograms), although secondary ion mass spectrometry has the potential sensitivity. Therefore, for the studies performed so far, microgram masses of analyte have been used and thus there is an uncertainty involved in interpreting the results. Condensation effects and associated back-reactions on the surface make extrapolation of the results to the pre-quenched, high-temperature conditions unreliable.

The most frequently used analytical technique for the identification of gaseous precursors to free analyte atoms is mass spectrometry (MS). Although *in situ* measurements are not possible, the ET atomizer vapor phase can be readily sampled and transferred to the MS detector online, allowing documentation of the actual vaporization- and atomization-related

**Figure 5** Some analytical techniques for the investigation of atomization mechanisms. MAS, molecular absorption spectrometry; MS, mass spectrometry; XRD, X-ray diffraction; XRPS, X-ray photoelectron spectrometry; RBS, Rutherford backscattering spectrometry; SEM, scanning electron microscopy; SIMS, secondary ion mass spectrometry.

processes, using analytically relevant masses, to be provided on the same timescale, but after a certain delay. Initial studies were performed with the ET atomizer held in vacuum, yielding information on the analyte species vaporized from the sampling site. Due to the extremely long mean free paths associated with vacuum conditions, homogeneous and heterogeneous interactions of gaseous analyte species are restricted. Measurements made at atmospheric pressure in the ET atomizer provide additional information on reactions occurring in the gas phase and following collisions with the graphite surface. A selection of the elements studied and the atomization mechanisms elucidated using MS is given in Table 1.

The simplest and most straightforward technique for *in situ* measurement of gaseous species is molecular absorption spectrometry (MAS). However, application of MAS is hindered by the poor sensitivity of the technique and the requirement for high-resolution spectrometers for the identification of the molecular species on the basis of their band structure. In addition, for many of the potentially interesting species suitable absorption lines and reference data are lacking.

Both AAS and MAS have been used to study the radial distribution of analyte species, as a function of temperature and time, in the ET atomizer. Such measurements provide data on the interaction of analyte species with the tube wall and on the effect of air ingress through the injection port.

## Modeling of Atomization Processes

The energy involved in the rate-limiting step of the atomization process can be derived from the initial part of the transient absorbance versus time plot, according to the Arrhenius equation

$$\ln A_t = E_a/RT + A_0 \quad [2]$$

where  $A_t$  is the absorbance at time  $t$ ,  $E_a$  is the activation energy involved in the formation of free atoms ( $\text{kJ mol}^{-1}$ ),  $R$  is the gas constant ( $\text{kJ mol}^{-1} \text{K}^{-1}$ ),  $T$  is the temperature (K), and  $A_0$  is a constant.  $E_a$  is then compared with tabulated thermodynamic data, for example, the enthalpy of evaporation of the material. Similarities in these energy values are often used in postulating on the mechanism governing the appearance of atoms in the gas phase. Several models have been evaluated to determine the order of release in the analyte atom formation process. One of them is a visual method to derive the order of release by comparing various absorbance profiles obtained for different concentrations of analyte assuming that the activation energy is not dependent upon the covered surface in the atomization time interval and from changes of the temperature at the peak maximum. However, conclusions were that the activation energy and the order of release derived from the method are often subjective as the order of release providing the most extended linear range on data sets has to be selected.

In addition, the order of release and the activation energy may significantly vary with analyte concentration; and the temperatures with the time of maximum absorbance are not suitable parameters to correlate with the order of release for the atomization process.

The use of various absorbance profiles for different analyte concentrations has been applied, with activation energy independent of the amount of analyte. In this case, the main problem was due to the fact that the order of release and the activation energy were deduced from different and in many cases very short temperature ranges. Beside the adsorption/desorption processes, a second modeling approach based on condensation/evaporation processes have been proposed where some features of the atomization process are also interpreted – double values of the activation energy, values of  $E_a < \Delta H_T$ , the origin of the empirical relationship between  $E_a$  and  $T_{\text{app}}$  (appearance) as well as the theoretical activation energies and preexponential factors.

A method based on Maxwell's theory with broad temperature range of applicability has also been proposed assuming that the vaporization rate of material

<sup>a</sup>s, l, g, and ad are solid, liquid, gaseous, and adsorbed species, respectively.<sup>b</sup>AlO and Al<sub>2</sub>O are formed as well.

from graphite surface depends on the number of atoms having an higher energy than the energy of vaporization process. As Maxwell's theory, the model has been developed on the basis of probability arguments, using one single absorbance signal under nonisothermal conditions and considers the dissipation of the analyte atoms from the simultaneous contribution of the diffusion, thermal expansion, and redeposition processes. If more than one precursor generates the atomic vapor resulting in two or more resolved pulses, the method can independently be applied to each pulse. The main advantages of the method are (1) the activation energy can be evaluated without the need to know the order of release of the

analyte atom formation process and (2) the calculation of the activation energy can be possible in any moment of the atomization process, which means that the method uses virtually ~100% of the rising edge of the peak and not necessarily at the first moment of the absorbance–time profile.

High-temperature equilibrium calculations (HTECs) are useful for studying complex chemical systems, and they enable the simultaneous investigation of condensed and gaseous phases. For the calculations general computer programs are used, and the equilibrium compositions in the solid, liquid, and ideal gas phases are calculated for the given amounts of the elements assumed to be present in the system (input

amounts) using the free-energy minimization principle. Reliable equilibrium compositions for a multi-component system can be obtained provided that accurate thermodynamic data are available for all possible species that may be formed, and that reactions are sufficiently rapid to attain a state close to equilibrium. The latter condition is mainly determined by temperature, time, and the concentrations of the elements present. In ET atomizers, reaction products are continuously removed during heating by convection and diffusion, which complicates the selection of the initial input amounts of the elements constituting the system. A second problem is that some reactions, in particular heterogeneous reactions, may be kinetically controlled, as described above for the reaction between carbon and oxygen below 2000 K. Allowance for such reactions can be made in the program. Advantages of HTECs are that predictions of the effects of varying input amounts on the occurrence of interferences can be made, and complicated chemical systems can be modeled. However, spatial concentration gradients or kinetically driven reactions cannot be accounted for.

A model for the reduction of oxides by gaseous carbides (ROC model) has been proposed. The model involves the formation of metal carbides at the graphite surface, gas-phase transport of these carbides to the metal oxides, reduction of the oxides, and generation of free atoms and carbon monoxide. The reaction is self-sustained through further reactions between the free atoms and carbon.

**Table 1** summarizes a selection of proposed atomization mechanisms. That there is no consensus of opinion is a reflection on the weaknesses of the models and techniques used to investigate the complex reactions involved in atom formation. There is a clear need to develop methods that would help to identify *in situ* the condensed or adsorbed species that are present on the graphite surface.

## Occurrence and Elimination of Nonspectral Interference Effects

By definition, an interference effect occurs when the analytical signal is changed by the sample matrix compared with the reference or calibration standard, typically an acidified aqueous solution. This article is only concerned with nonspectral interferences in ET-AAS; spectral interferences are considered elsewhere. It has been demonstrated in ET-AAS that the atomization efficiency (conversion of analyte to free atoms) is  $\sim 100\%$  for the majority of elements in simple solutions, which means that, in most cases, only negative nonspectral interferences can occur, i.e., the signal can only be reduced by the presence of

a matrix. The types of interference and their elimination are discussed below. It is assumed that standards and samples are quantitatively transferred to the intended location and are dried smoothly without sputtering and irreproducible spreading. Otherwise problems may arise from the resultant variation in the distribution of sample within the atomizer, particularly when the tube is not heated homogeneously over its length. The influence of the magnetic field on complex absorption patterns has also been recorded with high temporal and spatial resolutions, which enables the further investigation of potential spectral interferences in Zeeman-AAS measurements.

## Recent Instrumental Developments in Electrothermal Atomic Absorption Spectrometry

Although instrumental developments are mainly in the hands of manufacturers, research field has proposed the use of continuum light sources instead of hollow cathode lamps to develop multielement systems. Coupling xenon short-arc lamp, double-echelle monochromator or CCD detector to electrothermal vaporization (ETV) proved to extend spectral resolution main as atomic absorption can be measured not only at the center of the absorption line (with maximum sensitivity), but also in its wings (with reduced sensitivity). The dynamic range of determination increased to five to six orders of magnitude, thus eliminating the classical disadvantage of the technique – the limited dynamic range. CCD detectors also provide extra information about the spectral neighborhood of the analytical line in question, resulting in more reliable and accurate background correction than in the case of applying deuterium lamp or Zeeman background correction, especially for difficult spectra. Applying a continuum source atomic absorption system the Zeeman-splitting of the analytical lines can be also be measured in the range of 190–900 nm, providing a good agreement between the theoretical and experimental values of the spilling lines. The capabilities of AAS have undoubtedly been extended with continuum light sources – turning a traditionally single-element technique into a multielement technique. With the replacement of the one-dimensional multiarray detector by a two-dimensional multiarray detector the simultaneous multielement version is to follow and gain acceptance.

## Stabilized Temperature Platform Furnace Concept

This concept should probably be referred to as the stabilized temperature platform atomizer, in line with recent International Union of Pure and Applied Chemists nomenclature recommendations, but will

be called stabilized temperature platform furnace concept (STPF) in the following to conform to the current literature.

Other than the use of the platform (see above), the STPF concept incorporates a number of methodological and instrumental improvements that give conditions approximating to those of a constant temperature atomizer:

1. Rapid heating of the atomizer to make sure that the sample is vaporized from the platform only after the tube has reached its final temperature.
2. Use of modifiers (see below) to stabilize the analyte during thermal pretreatment, to delay volatilization until the temperature in the atomizer is sufficiently high and stable for efficient atomization, and to buffer the composition of the gaseous phase.
3. Stopping the gas flow during the atomization step to attain maximum sensitivity (gas stop conditions).
4. Quantification only with integrated absorbances. Provided that the temperature of the vapor phase is constant, this eliminates the effects of matrix-induced changes in the rate of atom formation, which alter the peak height. Constant temperature is most nearly achieved by using the platform.
5. A short response time of the measurement system to monitor accurately the rapidly changing signal profile.
6. An efficient background correction system.

#### Losses of Analyte During Thermal Pretreatment

Many analytes may form volatile species with other elements in the sample, for example, halides, or be present in compounds that exhibit high-vapor pressures at relatively low temperatures (mercury, arsenic, selenium, organometallics). Such compounds may be volatilized and swept from the tube, in molecular form, prior to the atomization step. These losses can be dealt with by adding a large excess of a reagent (a modifier) to change, *in situ*, the thermochemical behavior of the analyte and the matrix.

**Matrix removal** Volynsky grouped the chemical modifiers applied in ETV-AAS analyses as follows:

- Pd containing modifiers, e.g.,  $\text{Pd}(\text{NO}_3)_2$ ;
- organic acids, e.g., ascorbic, oxalic, and tartaric acids;
- organic-metal complexing reagents, e.g., ethylenediaminetetraacetic acid, cupferron, 1-(2-pyridylazo)naphthol, 1-(2-pyridylazo)resorcinol, 2-(5-bromo-2-pyridylazo)-5-(diethyl-amino-phenol);
- phosphates, e.g.,  $\text{NH}_4\text{H}_2\text{PO}_4$  and  $(\text{NH}_4)_2\text{PO}_4$ ;

- nitrates, e.g.,  $\text{NH}_4\text{NO}_3$ ,  $\text{AgNO}_3$ ,  $\text{KNO}_3$ ,  $\text{Sr}(\text{NO}_3)_2$ , and  $\text{Mg}(\text{NO}_3)_2$ .

However, matrix modification has always been a topic attracting attention and providing a wide variety of choices and not necessarily consistent results.

#### Changes in Atomization Efficiency and Atomic Residence Time

Despite the use of modifiers and stabilized temperature conditions, it is not always possible to remove the matrix completely or to achieve sufficiently high temperatures to ensure complete atomization. Some analytes form extremely thermally stable oxides, carbides, hydrides, halides and sulfides; intermetallic molecules can also be formed during the vaporization of metal matrices, thus reducing the atomization efficiency. In end-heated ET atomizers (see Figure 1a), it is possible for matrix species to condense at the water-cooled tube ends. The analytical signal may then decrease because the analyte residence time in the vapor phase is diminished through interaction between these trapped matrix species and the gaseous analyte atoms. This interference effect is eliminated in spatially isothermal, side-heated atomizers (Figure 1b).

The rate of diffusional losses of atoms can be changed by matrix vapors, if present at sufficiently high pressures at the same time as analyte, and if the diffusion coefficient of the analyte in the inert gas (argon) and in the matrix containing vapor differ appreciably. Since the diffusion coefficient in most matrix vapors is likely to be less than that in argon, this will result in a positive interference. The effect of this is rather small, however, since the gas phase will consist of an argon-matrix vapor mixture.

It should be noted that the interference effects discussed above can be corrected for using the standard additions method combined with the STPF concept.

#### ET-AAS Performance and Applications

Using STPF conditions, the instrumental response is reasonably stable, both between atomizers of the same type and on a day-to-day basis. As a measure of the response the term 'characteristic mass', symbolized by  $m_o$  (pg), has been introduced. This is defined as the absolute mass of analyte yielding an integrated absorbance of 0.0044 s. Characteristic mass values are provided by the instrument manufacturers to specify the performance of the ET-AAS equipment, and can be used to check that certain vital parts of the system (atomizer, light source) are functioning

**Table 2** Characteristics of the ET-AAS technique using STPF conditions

Sample requirement	5–100 $\mu\text{l}$ per determination
Time per determination	30–200 s
Detection limits	
Absolute	Picogram to nanogram
Relative	0.01–100 $\mu\text{g l}^{-1}$
Number of elements	~ 65 (single-element technique)
Analytical working range	2–3 orders of magnitude (nonlinear)
Interference effects	Small if matrix <0.1%

properly. It must be stressed that the characteristic mass should not be used as the only criterion for assessing ET-AAS performance and comparing different instrument systems. For practical ET-AAS work, requiring accurate and precise results, the atomization efficiency, low susceptibility to interference effects, and good detection limits are decisive factors.

Table 2 summarizes some of the important features of the ET-AAS technique using STPF conditions. For end-heated atomizers (see Figure 1a), the platform cannot be used in the determination of elements of low volatility like molybdenum, titanium, and vanadium. However, all elements can be determined using STPF conditions in side-heated atomizers (Figure 1b). Other than the characteristics shown in Table 2, it should be mentioned that modern ET-AAS instruments are fully automated and can work unattended, but experienced personnel are required to optimize parameters (particularly the temperature program) and ensure the quality of the results.

Although the analytical working range may extend to three orders of magnitude, a direct linear relationship between concentration and peak area is typically limited to one or two decades. This obviously leads to problems in applying the standard additions method. However, the replacement of hollow cathode lamps with continuum light sources has brought about improvements, extending the dynamic range of determination to five to six orders of magnitude.

Since ET-AAS is a trace element technique, special equipment is required to minimize the risks for contamination or analyte loss at the critical sample preparation stage of the analytical procedure. To minimize blank levels, additions of reagents to the sample should be limited, and for this reason dissolution techniques such as oxygen combustion and microwave-assisted wet digestion in closed cells are to be recommended. Sulfur- and halide-containing reagents may cause interferences in the determination of certain elements by ET-AAS and should thus be avoided.

ET-AAS is most often applied to the analysis of liquid samples. However, it is also possible to analyze

solids directly, by making use of the specially designed graphite tubes that are available. This approach avoids potentially difficult and time-consuming sample dissolution, and allows the study of the distribution of analyte in the parent material. Limitations include the presence of high concentrations of matrix that may exacerbate interference effects, problems with calibration, and labor-intensive sample introduction, even though attempts have been made to automate solid sampling ET-AAS for routine applications.

Introduction of slurried samples into ET-AAS is widely used for a range of sample types; automatic systems for this sampling procedure are also available.

Advantages of this approach include the possibility of diluting the sample if required, ease of automation, and greater flexibility in the choice of calibration technique.

### ***In Situ* Enrichment and Hybrid Techniques**

Graphite tubes can be used as both the trapping medium and the atomization cell for analytes that can be converted to a volatile species. This approach has a number of attractive features. First, very large sample volumes can be employed for one determination, giving very low detection limits. Second, the analyte is separated from the sample matrix, reducing potential interference problems. Third, atomization can be performed under gas-stop conditions maximizing sensitivity, unlike conventional flow-through cells, and, finally, relatively high temperatures can be used to ensure efficient atomization and conditioning of the tube, which is not possible with quartz tube atomizers.

The combination of hydride generation with ET-AAS has been utilized for arsenic, bismuth, germanium, antimony, selenium, tin, and tellurium, enabling reliable trace element determinations to be performed at the nanogram per liter level. Recent work has demonstrated the improved hydride collection efficiency obtained using palladium-treated graphite surfaces. Attempts to extend the range of analytes amenable to *in situ* enrichment in a graphite tube have resulted in procedures for the generation of nickel carbonyl and tetraethyl lead. It is also possible to reduce mercury species and collect the liberated mercury vapor in tubes coated with gold or lined with platinum gauze.

Flow-injection online preconcentration and separation with ion exchange or sorbent extraction in packed microcolumns and/or precipitation and collection in knotted reactors has proved to extend the capabilities of ET-AAS by allowing relative detection limits to be lowered by two to three orders of magnitude and troublesome matrices to be removed.

ET-AAS has been used as an element-specific detector for gas chromatography using a continuously heated atomizer. One problem with this approach is that the gaseous effluent purges the atomizer volume, decreasing sensitivity. For liquid chromatography (LC), there is an acute requirement for sensitive and specific detectors. However, attempts to couple LC to ET-AAS are difficult, due to the continuous liquid flow supplied by the former, and the discrete sampling mode of the latter. The coupling can be made using a thermospray interface, but vaporization and thermal expansion of the mobile phase entering the heated atomizer again reduces sensitivity. Improvements in LC coupled to ET-AAS may be envisaged using desolvation devices.

Obviously the use of ET-AAS detectors in chromatographic applications is limited to the determination of metal- and metalloid-containing species.

ETV may also serve as sample introduction for inductively coupled plasma (ICP)-atomic emission spectroscopy (AES)/MS providing the possibility of *in situ* sample preparation by selective vaporization of different sample components, using appropriate heating programs. By the reduction/elimination of matrix components, spectral interferences can be minimized and matrix effects in the plasma decreased.

ETV with solid sampling has shown its potential in speciation analysis by separating species according to their volatility. The suitability for the direct and simultaneous determination of methylmercury and inorganic mercury in ETV-ICP-ID-MS coupling has been presented. However, the drawback of the application is the difficulty of achieving proper calibration of all the species involved, and thus, less straightforward two-step approaches based on the use of two different temperature programs (one for the determination of the less volatile species after sample pretreatment and selective removal at low temperatures of the more volatile one) have also been proposed.

## Vapor Generation

## Introduction

The generation of gaseous analytes and their introduction into atomization cells offers several

significant advantages over conventional solution-phase nebulization of samples. These include the elimination of the need for a nebulizer, enhancement of transport efficiency (approaching 100%), and the presentation of a homogeneous vapor to the atomizer. In addition to the widely practiced techniques of covalent hydride generation and mercury cold-vapor formation, which comprise the subject of this article, mention must also be made of the successful

generation and introduction of volatile chlorides (Bi, Cd, Ge, Mo, Pb, Sn, Tl, As, and Zn),  $\beta$ -diketonates (Cr, Fe, Zn, Co, Mn, Cu, Ni, and Pb), and dithiocarbamates (Co and Cu) into atomization cells. Additionally, ethylation, propylation, and phenylation (Sn, Pb, Se, and Hg) as well as carbonylation (Ni) reactions have been implemented.

Hydride generation (and cold-vapor) techniques significantly improve atomic absorption spectrometry (AAS) concentration detection limits while offering several advantages: (1) separation of the analyte from the matrix is achieved which invariably leads to improved accuracy of determination; (2) preconcentration is easily implemented; (3) simple chemical speciation may be discerned in many cases; and (4) the procedures are amenable to automation. Disadvantages with the approach that are frequently cited include interferences from concomitant elements (notably transition metals), pH effects, oxidation state influences (which may be advantageously used for speciation) and gas-phase atomization interferences (mutual effect from other hydrides).

Hydride generation in AAS became popular after 1970 in response to a study by Holak, which demonstrated the analytical potential of this approach for arsenic. Since then, elements of groups IVA, VA, and VIA of the periodic table have been shown to form volatile covalent hydrogen compounds with sufficient efficiency to be of practical analytical use. These include arsenic, bismuth, germanium, lead, antimony, selenium, tin, tellurium, and to some extent, indium and thallium.

Although the determination of mercury in air by absorption spectroscopy was practiced before the advent of AAS, significant utilization of the cold-vapor technique arose during the 1960s (following the work of Hatch and Ott) and has continued, essentially unaltered in procedure, to the present.

Hydride generation and cold-vapor techniques may be conveniently characterized by three steps: (1) generation of the volatile analyte; (2) its collection (if necessary) and transfer to the atomizer; and (3) decomposition to the gaseous metal atoms (unnecessary for mercury) with measurement of the AA response. Each of these steps will be briefly reviewed prior to considering the analytical performance of these techniques.

## Formation of Covalent Hydrides and Mercury Vapor

Although several reactions have been utilized for the production of the hydrides, all rely on the formation of atomic hydrogen as a reductant. The classical metal-acid reaction employing  $\text{Zn-HCl}$  is limited to

the generation of  $\text{AsH}_3$ ,  $\text{SbH}_3$ , and  $\text{SeH}_2$ :

where E is the analyte element and  $m$  may or may not equal  $n$ . This system requires that these analytes be present in their lower oxidation states prior to reaction (otherwise they must be prereduced by addition of  $\text{SnCl}_2$  and KI to the acidified sample). Zinc metal is then added and the hydrides, along with excess hydrogen, are evolved. The reaction is slow, difficult to automate, suffers from large blanks due to impurities in the zinc, and is inefficient as a result of incomplete reaction and/or entrapment of the hydride in the precipitated zinc sludge. These factors, along with the availability of more effective reducing agents (such as sodium tetrahydroborate) have served to all but eliminate use of this approach.

Reduction to the hydride with sodium tetrahydroborate via reaction [II] is considerably more efficient:

and can be used to generate the hydrides of antimony, arsenic, bismuth, germanium, lead, selenium, tellurium, and tin. It should be noted that the participation of 'nascent' hydrogen in reaction [II] is currently considered improbable. In addition to increased elemental coverage, this reduction method is superior with respect to efficiency, speed, and reduced contamination. Reaction times are believed to be in the range of 10–30 s, although decomposition of the tetrahydroborate reagent is thought to be complete in a fraction of a second under acidic conditions. Although initially added to acidified samples in the form of solid pellets, this reagent is now almost exclusively dosed into acidified samples as a 0.1–10% (m/v) solution, lending itself to ease of automation. The reagent is somewhat unstable and it is often recommended that it be prepared for storage by the addition of NaOH or KOH at concentrations of 0.1–2%. Others suggest that it be prepared fresh daily, filtered through membrane filters or stored in a refrigerator.

Most recently, amineboranes of the type  $\text{L-BH}_3$  (where  $\text{L} = \text{NH}_3$ ; *tert*- $\text{BuNH}_2$ ;  $\text{Me}_2\text{NH}$ ;  $\text{Me}_3\text{N}$ ) and sodium cyanotrihydroborate(III) ( $\text{NaBH}_3\text{CN}$ ) have been tested for efficacy of generation of elemental mercury and volatile hydrides of As(III), As(V), Sb(III), Sb(V), Bi(III), Se(IV), Se(VI), Te(IV), and Te(VI). All of the reductants are suitable for efficient generation of cold-vapor mercury but only some of the amineboranes are suitable for hydride generation,

with Se(VI) and Te(VI) remaining unreactive. Reducing power follows the order:  $\text{NaBH}_4 > \text{H}_3\text{N}-\text{BH}_3 > \text{tert-BuNH}_2-\text{BH}_3 > \text{NaBH}_3\text{CN} \geq \text{Me}_2\text{HN}-\text{BH}_3 > \text{Me}_3\text{N}-\text{BH}_3$ . Of note is that the amineboranes and cyanotrihydroborate(III) provide for better control over interferences from Fe(III), Ni(II), Co(II), and Cu(II) than  $\text{NaBH}_4$ . These systems remain to be more thoroughly investigated, especially from an applications viewpoint.

Although aqueous systems are the most frequently encountered, the hydrides of some elements (antimony, lead, and tin) have also been generated directly from nonaqueous media (*N,N*-dimethylformamide, DMF) by the addition of  $\text{NaBH}_4$ /DMF solution as reductant.

Hydrochloric acid remains the acid of choice, although  $\text{H}_2\text{SO}_4$  and  $\text{HNO}_3$  have also been used in generation media. Optimum acidity ranges depend on the element and are also often tailored to suit specific matrices, i.e.,  $1\text{--}9\text{ mol l}^{-1}$  for antimony, arsenic, and bismuth;  $1\text{--}3\text{ mol l}^{-1}$  for germanium;  $0.1\text{--}0.2\text{ mol l}^{-1}$  for tin and lead;  $2.5\text{--}5\text{ mol l}^{-1}$  for selenium; and  $2.5\text{--}3.6\text{ mol l}^{-1}$  for tellurium. Additional constraints enter into the generation of  $\text{PbH}_2$  wherein oxidizing agents such as  $\text{KCr}_2\text{O}_7$ ,  $\text{H}_2\text{O}_2$ ,  $(\text{NH}_4)_2\text{S}_2\text{O}_8$ ,  $\text{Ce}(\text{SO}_4)_2$ , or  $\text{KMnO}_4$  are frequently added to the solution to create lead(IV) intermediate in order to enhance the efficiency of conversion.

The above reduction technique is not used with impunity, including the introduction of contamination (notably tin), interferences from concomitant transition metal ions and the evolution of excessive hydrogen (not considered a problem for AAS detection but potentially detrimental to plasma source atomic spectrometric techniques).

Although infrequently used, electrochemical generation of the hydrides is also possible and has been applied to the determination of arsenic and tin in a batch approach and to antimony, arsenic, germanium, selenium, and tin using a flow-through electrolytic cell. The hydride is generated in the cathodic space of an electrolytic cell, with concurrent oxidation of water in the anodic compartment, as illustrated by the reaction below. Here, Me-E represents the reduced analyte element on the metallic cathode surface (Me):

A high mass transfer rate of the analyte to the cathode surface is required for optimum efficiency. Batch sampling, continuous flow, and flow injection (FI) solution delivery coupled with batch reactors, thin-layer membrane separator designs, and tubular cells have been examined. Although no significant

gain is evident with respect to interferences, minimization of contamination through elimination of chemical reducing reagent is possible, offering the lure of ever lower detection limits. Electrochemical generation is reported to be less subject to oxidation state influence, exhibit greater freedom from interferences arising from concomitant elements, and liberate less excess hydrogen than homogeneous generation reactions based on tetrahydroborate(III).

Thermochemical generation of hydrides appears feasible and has been utilized for the determination of arsenic species in the effluent from a liquid chromatograph. It is based on the injection of a thermospray aerosol into a methanol/oxygen flame where pyrolysis of the eluate occurs with subsequent thermochemical derivatization of the analytes and their transfer to a cool hydrogen-rich  $\text{H}_2/\text{O}_2$  diffusion flame for atomization/AAS detection.

More recently, photo-induced generation of the hydrides has been reported utilizing UV-irradiation of the sample in an aqueous medium spiked with low molecular weight acids such as formic, acetic, malonic, etc. The efficiency of the process is greater than 70% for Se and, depending on the species in solution, radical reactions can give rise to various products, including the simple hydrides or alkylated derivatives, as outlined below:

It is self-evident that use of formic acid gives rise to the hydride species. Early results suggest that a number of elements are amenable to such a reaction, including As, Pb, Hg, etc.

Cold-vapor AAS (CV-AAS) occurs in a manner similar to hydride generation AAS in that elemental mercury is formed in solution by reduction to  $\text{Hg}^0$  followed by transport to and detection in an absorption cell. Simple first-order speciation of this element may be achieved using  $\text{SnCl}_2$  under acidic conditions to selectively reduce inorganic mercury, and under basic conditions in the presence of copper(II) ion to reduce both inorganic and organomercury compounds. Until recently, tin(II) chloride solution (5–10% m/v) was almost exclusively used for the reduction of mercury. Currently,  $\text{NaBH}_4$  is finding increasing application for this purpose and it has been suggested that selective reduction of inorganic mercury can be achieved using  $\text{SnCl}_2$  at basic pH followed by subsequent reduction of organomercury compounds in the same solution by addition of  $\text{NaBH}_4$ . This latter reagent also presents the advantage of faster liberation of the mercury from the solution phase and, in some cases, reduced interferences.

Sodium tetrahydroborate is also attractive because of its comprehensive nature in that generation of mercury as well as all other covalent hydrides of interest can be accomplished in the same reaction vessel.

## Vapor Generator

### Hydrides

The hydride that is formed is flushed from the generating chamber with argon, helium, or nitrogen. There are essentially three methods used to generate hydrides with  $\text{NaBH}_4$ : (1) continuous systems where sample and reagent are pumped and mixed in a continuous fashion and then passed to some type of gas-liquid separation device; (2) batch systems, wherein a pellet of  $\text{NaBH}_4$  or an aliquot of the reductant solution is added to the sample from which the volatile products are purged with a flow of transfer gas; and (3) FI systems in which discrete volumes of sample are merged with flowing streams of acid and/or reductant. These three arrangements are illustrated in **Figure 1**. Although automation is easily implemented and precision of measurement is often improved with continuous sampling as a result of the steady-state signals, this approach is at present little used with the AAS detection mode. Mixing coils, frequently inserted into flowing reaction systems, are useful only in that they aid in the phase separation of the hydride prior to entry into the actual gas-liquid separator. Such coils are generally not needed to increase the reaction time and in some cases have been shown to have a detrimental effect in that an enhancement in interference is observed. Gas-liquid phase separators have included simple arrangements, such as that illustrated in **Figure 1**, in addition to various

hydrophobic membrane-based systems which provide for dry gas streams as well as shorter response and memory times.

The hydride technique is an absolute procedure in that the measured response is directly proportional to the absolute mass of the analyte element and not to its concentration in the solution. In practice, an aliquot of acid is usually added to the batch vessel followed by an accurately dispensed volume of sample. Depending on the apparatus used, peak-height quantitation may exhibit some sample volume dependence but this is absent when signal integration is used. Most batch reaction vessels for the hydride technique accept a relatively large sample volume (1–50 ml) whereas online FI techniques are flexible in that variable sample loop volumes or timed sample pumping can be used to deliver an almost continuous distribution of desired volumes (typically 0.1–10 ml). FI offers a number of distinct improvements over the batch technique, such as high absolute sensitivity, reduced sample and reagent consumption, reduced interference effects, ease of incorporation of elaborate sample pretreatment, high sampling frequency, and ease of automation. A singular disadvantage remains the small volumes that, compared with batch systems, results in inferior relative sensitivity. As this is more than compensated for by the greater freedom from interferences and high absolute sensitivity, FI techniques are to be preferred for the analysis of real samples.

The transient hydride plume produced by either the batch or FI approach may be directly transferred to the atomization cell because reduction reactions are sufficiently rapid. Alternatively, the hydride is frequently collected in a cold trap (usually a cryogenic U-tube filled with a suitable adsorbent that is subsequently warmed to desorb the analyte) connected to the generator via a  $\text{CaCl}_2$  drying tube, absorbed in solutions of  $\text{AgNO}_3$ , Ag-diethyldithiocarbamate,  $\text{KI/I}_2$ ,  $\text{Ce(IV)/KI}$ , and  $\text{I}_2$  (for subsequent quantification by graphite furnace AAS), or sequestered directly in a preheated graphite furnace prior to atomization/quantitation. These latter schemes permit significant additional preconcentration factors to be achieved while often eliminating or minimizing interferences associated with the generation step (generation kinetics). Most recently, the application of solid-phase microextraction fibers has permitted sampling of the evolved vapors for subsequent desorption and introduction into suitable detectors (such as ICPs and EI-MS sources).

Several new approaches to the generation of the hydrides have recently come to the attention of the analytical community. One utilizes an anion exchanger, in the tetrahydroborate form, packed as a

**Figure 1** Hydride generation approaches: (A) continuous generation; (B) batch generation; and (C) flow injection.

bed in the liquid channel of a gas–liquid separation membrane cell. FI-pumping of an acidic sample through the cell results in the heterogeneous production of hydrides that are rapidly transferred to the measurement cell. The extent of some interference effects is reduced with this arrangement.

Recently, attention has focused on taking advantage of the rapid generation kinetics of the tetrahydroborate–acid reduction reaction to expand the suite of elements amenable to hydride generation. These include the use of a moving bed generator as well as modified parallel path concentric and cross-flow nebulizers, as illustrated in **Figure 2**. Rapid interaction of sample with reductant, while providing for instantaneous gas–liquid separation achieved with these systems, offer the potential for reduction or elimination of interferences from concomitant species in solution. Successful generation of a number of ‘unconventional’ volatile species by reaction of acidified sample solutions with sodium tetrahydroborate has now been reported to include (in addition to Cd and Hg and the classical hydride forming elements): Cu, Ag, Au, Zn, Ni, Pd, Rh, Pt, Ti, Ir, Mn, Co, Fe, and Cr. Little is known of these species, except that they are relatively unstable, requiring rapid gas–liquid or gas–solid separation techniques, and they appear to be molecular in nature. The full scope of elements amenable to such reactions is currently unknown. Reported generation efficiencies range from greater than 50% to less than 1%. Only minimal analytical use of these approaches has been reported to date.

Combined generators, which are designed to take advantage of conventional introduction of liquid samples into atomization sources (such as the inductively coupled argon plasma, or emission or mass spectrometric detection of the analyte) along with simultaneous generation/introduction of the hydride forming elements, have also been proposed. These are usually based on a conventional or modified spray chamber that permits introduction of reductant through an additional channel, permitting its interaction with the acidified sample aerosol.

### Cold Vapor

Mercury is the only metallic element that is liquid at room temperature and possesses a significant vapor pressure. As a result of these unique properties, mercury can be determined without an atomization cell simply by reducing it to the elemental state and transferring it to the vapor phase within the optical path of a suitable detection system. Absorption is usually measured at the 253.7 nm resonance line. Similar to hydride generation, the majority of such

**Figure 2** Hydride generation systems: (A) movable bed generator (Reproduced with permission from Tian X-D, Zhuang Z-X, Chen B, and Wang W-R (1998) Movable reduction bed hydride generator coupled with ICP-OES for the determination of some hydride forming elements. *Analysts* 123: 627–632.); (B) modified Meinhard concentric nebulizer; and (C) cross flow nebulizer.

**Figure 3** Typical cold-vapor mercury generation system.

determinations is usually accomplished using batch procedures, although FI systems are now enjoying more widespread usage. **Figure 3** illustrates a typical mercury generation system. Tin(II) chloride historically remains the preferred reductant; although  $\text{NaBH}_4$  is a more powerful reducing agent, its use may increase the risk of certain interferences. These include excessive water droplet formation and carry-over as potential poisoning of amalgamation traps due to cogenerated hydrides if certain precautions are not undertaken. Use of  $5 \text{ mol l}^{-1}$  HCl in the presence of  $200 \text{ mg l}^{-1}$  Fe(III), an alkaline gas wash bottle to eliminate cogenerated  $\text{SeH}_2$ , a drying agent ( $\text{Mg}(\text{ClO}_4)_2$ ) and, most importantly, ensuring that the amalgamation trap is below  $100^\circ\text{C}$  during collection (otherwise it suffers gradual poisoning) serve to minimize such problems. Helium is preferred over other gases as the most efficient sparging and transfer medium and an inline glass fiber filter is often used in place of the chemical desiccant (when  $\text{SnCl}_2$  is used as the reductant) to remove any fine water droplets from the carrier stream (water vapor does not interfere with the absorption detection of mercury). Particular care must be taken in the selection of vessels and tubing in such apparatus due to the mobility and reactivity of mercury. Quartz ware and fluorinated ethylene propylene are often advised because they can be easily cleaned, are nonpermeable, and exhibit little affinity for adsorption of mercury. Polytetrafluoroethylene (PTFE) tubing is superior to other materials for the transfer of mercury vapor.

As with hydride generation, the evolved mercury vapor can either be transferred directly to the optical cell for measurement or trapped for later release. As the mercury is normally liberated slowly from solution over a period of 1–2 min, low intensity signals are generated; consequently, vapor trapping is frequently used to improve concentration detection limits for solution analysis. Enhanced separation and concentration of mercury is usually achieved by amalgamation on a noble metal trap, from which it is subsequently thermally desorbed (at  $500\text{--}700^\circ\text{C}$ ).

Currently, a gold–platinum gauze (90% Au, 10% Pt) is found to be most useful for this purpose because of its performance characteristics, which include high surface area, physical stability, thermal conductivity, and ease of cleaning. These properties lead to optimal signal reproducibility and generally an increase in sensitivity by 10-fold. Occasionally, two-stage gold amalgamation procedures have been utilized wherein the thermally desorbed mercury is recollected on a ‘standardized’ gold trap, which has been carefully calibrated, and is then desorbed into the spectrometer/detector. Water vapor that has collected on the first trap can be evaporated and interferences due to organic compounds (if air sampling has been used) that are oxidized during the first desorption, are thereby avoided. Alternatively, the generated mercury can be directed into a standard graphite tube atomizer (for GF-AAS), which has been lined with Pt gauze to effect *in situ* preconcentration. Subsequent high temperature heating desorbs the mercury directly into the optical beam of the spectrometer, serving to further enhance sensitivity.

## Atomization and Detection

### Hydrides

Conventional acetylene-based flame systems have found little use as atomization cells for hydrides. The relatively cool argon (entrained air)–hydrogen or simple air–hydrogen flame is advantageous as it exhibits low background absorption at lower wavelengths (15% at  $193.7 \text{ nm}$ ). However, the excess hydrogen generated along with the hydrides often perturbs the flame, changing its composition and absorption characteristics, and the low kinetic temperature makes it more susceptible to interferences.

Currently, the most popular atomization source for hydride generation AAS is the heated quartz T-tube (typically  $10 \text{ mm}$  diameter  $\times$   $100\text{--}150 \text{ mm}$  length). Both argon–hydrogen and air–acetylene flames have been utilized to heat open-ended silica tubes to which the hydrides are delivered in a stream of carrier gas from the generator via the central arm of the T. The quartz tube can also be heated electrically ( $700\text{--}1000^\circ\text{C}$ ) with the advantage of longer analyte residence time in the optical path and the possibility of obtaining the optimum atomization temperature for each element. Often, the tube is sealed with removable quartz windows at either end and fitted with nipples at the extreme ends as exits for the gas flow. These features result in improved sensitivity over the flame heated cells. Deterioration and aging of the interior surface of the quartz tube invariably occurs, leading to a decrease in sensitivity

and precision. This has been attributed both to an irreversible devitrification of the quartz to a less satisfactory  $\beta$ -cristobalite structure and to contamination of the atomizer surface caused by deposition of liquid particles of the sample or small droplets that are carried from the generator into the tube. In the latter case, careful cleaning by soaking in 40% (m/v) HF often restores the sensitivity.

Also used for atomization sources are the flame-in-tube devices, in which the excess hydrogen generated during the reduction step is used to carry the hydrides to a T-shaped quartz tube. A small amount of oxygen or air is added to support the combustion of a small flame. Although more complicated than the simple quartz tube, this system does not exhibit any significant analytical advantages over the latter but has been found useful for mechanistic studies relating to atomization processes.

A recent, second generation modified flame-in-tube atomizer consisting of multiple miniflame ports located along the axis of the quartz tube provides for an extended region of active atomization to realize an enhanced absorption path length and reduced mutual interference effects from other cogenerated hydrides, as discussed later.

Continuously heated graphite furnaces have seen limited use as atomizers in which the hydride enters a preheated furnace (1800–2300°C) and is atomized during its transit time through the device. Although more bulky and difficult to operate, these systems offer a continuously clean and reproducible atomization surface, permit variable atomization temperatures to be used, and result in slightly improved limits of detection than those arising with the heated quartz tube. Tin, however, can suffer adsorption on any graphite transfer lines and reactions between water vapor, hydrogen, and graphite at high temperatures give rise to increased background absorption.

An alternative system that is attractive for batch generation techniques, particularly FI-based approaches, is the use of the graphite furnace as both

the preconcentration cell and atomizer. The liberated hydrides are swept by a stream of inert gas into a warm (300°C) graphite furnace and directed onto the surface of a small (4  $\mu$ g) previously reduced deposit of palladium which serves to catalytically decompose and trap the hydride. Following completion of the generation phase, the sequestered sample is atomized by cycling the furnace through a conventional high temperature heating program and the signal recorded. This approach permits additional preconcentration to be achieved, is less prone to interferences, can be optimized for individual elements, and readily permits Zeeman-based background correction to be implemented. Concentration detection limits are one to two orders of magnitude superior to all other hydride generation approaches.

In addition to these 'online' atomizers, the graphite furnace has also been used in its traditional role as an offline device for the analysis of conventional liquid samples of sequestered hydrides. Aliquots of absorbing solutions used to tap the generated hydrides are injected into the furnace, atomized and quantitated in the usual manner.

Detection systems employed with hydride generation approaches are conventional AA spectrometers, usually fitted with intense electrodeless discharge or hollow cathode lamp sources. Quartz tube cells are of suitable dimensions to be compatible with the optical systems of all modern spectrometers. Background correction is usually achieved in double-beam optics using deuterium sources, and Zeeman-effect background correction can be implemented when the graphite furnace is used as the atomization cell.

Table 1 summarizes the limits of detection of a number of hydride forming elements reported for the various generation–detection methods. For comparison with continuous sampling techniques, a 10 ml sample volume has been assumed for *in situ* trapping in the graphite furnace (although larger volumes are easily accommodated) and a 500  $\mu$ l volume for FI approaches. It is clear that, despite the small sample

**Table 1** Concentration detection limits ( $3\sigma$ ) given in nanogram per milliliter for hydride generation and cold-vapor AAS techniques

consumed for FI work, relative concentration detection limits are as good as those for continuous sampling. Additionally, 1000-fold improvements in detection power are readily achieved using *in situ* trapping.

### Cold Vapor

As the cold-vapor mercury sample is already in the atomic state, there is no need of an atomizer, *per se*. The vapor, transferred directly from the cell or desorbed as a plug from a heated amalgamation trap, is commonly swept into a moderately heated (resistance wound heating to 200°C) 10 cm quartz T-tube located within the optical beam of a conventional AA spectrometer. Attenuation of an intense electrodeless discharge lamp line source at 253.7 nm is used as a measure of the absorption. Alternatively, dedicated continuum source AA-based spectrometers fitted with long path absorption cells (30 cm) are frequently used to increase sensitivity and detection limit.

Similar to hydride generation, graphite furnaces may be used both as the trapping medium and the atomizer for mercury. This may be accomplished by directing the evolved mercury from the generation cell onto an amalgamation medium (a reduced solution of gold or a gold-palladium gauze) inserted into the graphite tube for *in situ* preconcentration. Detection limits are generally improved threefold over conventional amalgamation trapping-quartz tube detection systems. Table 1 summarizes the reported detection capabilities for mercury using these various approaches.

### Atomization Mechanisms

Atomization of the hydrides is currently believed to proceed via interaction with free hydrogen radicals; oxygen also plays an active role. In argon/hydrogen diffusion flames and quartz tube atomizers, a cloud of hydrogen radicals is formed by reactions between hydrogen and oxygen:

The concentration of hydrogen radicals is several orders of magnitude higher than that of hydroxy radicals. In the quartz tube, this occurs either in a flame burning at the end of an oxygen delivery capillary (for a flame-in-tube device) or at the beginning of the hot zone for an externally heated tube (above 600°C). Only a small portion of the volume of the atomizer is filled by the cloud, as determined by the gas dynamics, geometry of the tube and

its temperature profile. The hydride is atomized within the radical cloud in accord with sequential collisions:

The number of hydrogen radicals is primarily determined by the oxygen supply to the atomizer and, if insufficient, thermal decomposition of the hydride may occur (if the temperature is high) and lead to the formation of dimeric (and tetrameric for arsenic) species or, in the absence of hydrogen, to oxides, with consequent loss of sensitivity. Decreasing the inner diameter of the quartz tube serves to increase the radical cloud density but, as analyte atom attrition occurs predominantly by reaction with the quartz wall, the consequent less favorable surface area-to-volume ratio precludes any major enhancement in performance. Deterioration in sensitivity noted with tube aging may be accounted for by the formation of active sites, which serve to deplete the hydrogen radical concentration and/or scavenge analyte atoms.

Use of the multiple microflame quartz tube atomizer provides for a significant improvement in performance of this device. Recurrent analyte atomization occurs over the whole optical tube length, achieved by production of H-radicals at multiple points within the tube by oxygen microflames burning in the hydrogen-containing atmosphere. This feature serves to enhance the range of linearity in response to 200 µg/l for Se and Sb and 100 µg/l for As. A 10–100-fold improvement in tolerance to interferences from cogenerated analytes is also achieved.

It is believed that similar mechanisms are involved in the atomization from a graphite furnace operating in the direct transfer continuous mode of measurement. However, the probability of thermal dissociation increases substantially as the temperature of the source increases, with the result that radical mechanisms probably decline in significance above 2000°C. Atomization of the hydride elements trapped on reduced palladium within the graphite furnace appears to proceed at high temperature as a simple first-order desorption process from the surface of the deposit.

### Interferences

#### Hydrides

Chemical interferences may occur in the liquid phase during formation and release of the hydride or in the gas phase during its transport to the atomizer or

within the atomizer. The extent and severity of these interference effects vary widely and are dependent on the instrumentation and hydride generation system used. A 'physical' interference, often referred to as a kinetic interference, may arise as a result of a difference in the release rate of the hydride from solution due to a volume effect or perhaps to sample foaming. These interferences are only encountered in direct systems where the measurement is performed online; they do not occur when the hydride is collected.

Spectral interferences are essentially absent in hydride generation AAS because the analyte is completely separated from the sample matrix. Minor fluctuations that may occur in the baseline during sample introduction are easily compensated for with conventional background correction systems.

Although strictly 'chemical' in nature, oxidation state interferences are well recognized and generally easily dealt with. For elements of group IVA (germanium, tin, and lead), little is reported as to the influence of oxidation state on sensitivity, although it is clear that generation efficiency is remarkably enhanced for lead if reduction is performed in the presence of strong oxidizing agents (suggesting the formation of an intermediate Pb(IV) species). For elements of group VA (antimony, arsenic, and bismuth), the sensitivity difference in peak-height mode of quantitation is less than twofold for the +3 and +5 oxidation states. As bismuth exists virtually in the +3 state, there is no concern. Under sufficiently acidic conditions, response from both arsenic(III) and arsenic(V) is the same. On- or offline prereduction of the sample with KI-ascorbic acid or KI-HCl is easily implemented for both arsenic and antimony if the sample preparation or dilution steps preceding measurement did not leave the analyte in the trivalent state. For the elements of group VIA (selenium and tellurium), only the +4 oxidation state is reactive and prereduction is required. This is often accomplished using hot 4–6 mol l<sup>-1</sup> HCl. Advantage is frequently taken of the differential reactivity of the separate oxidation states of antimony, arsenic, and selenium to effect a first-order speciation of the element in the sample with respect to this parameter. This is easily implemented for antimony and arsenic simply by selectively generating the hydride from the +3 state at high pH and from both forms at low pH.

It is also important that the various chemical species of the analyte be converted to a common form. Some of the organoforms of these elements commonly found in biological fluids and tissues are inert toward hydride formation (e.g., selenomethionine and arsenobetaine) and care must be taken to ensure that the sample has been completely oxidized by,

for example: treatment with peroxydisulfate at pH 2 for organoselenium compounds; alkaline peroxydisulfate for arsenic; and a mixture of KBrO<sub>3</sub>-KBr-HCl for tin and bismuth (note that in all cases it is necessary to reduce all oxidation states 'back' to the lower valence state prior to analysis). Alternatively, sample analysis before and after extensive oxidative treatment again affords a further route for the methodologically defined speciation of the element. Additionally, methylarsonate and dimethylarsinate are reduced to methylarsine and dimethylarsine, respectively, and may be chromatographically determined following cryogenic trapping.

Few reports of the interference of acids (except HF) on the determination of the hydride forming elements have appeared. Only tin and lead exhibit a relatively strong pH dependence so that they are normally determined in buffered media. In most cases, dilute hydrochloric acid (<1 mol l<sup>-1</sup>) is preferred, as higher concentrations give rise to increased contamination.

Of the common metallic elements, significant interferences are encountered in the presence of high concentrations of other hydride forming elements, iron, copper, nickel, cobalt, and the platinum group elements. This effect is not dependent on the analyte-to-interferent ratio, but rather on the concentration of the interferent in the analysis solution. Although several theories exist to account for these effects, the consensus is that preferential reduction of the interfering ion occurs and the resulting finely dispersed precipitate scavenges (and decomposes) the hydride formed in the secondary reaction. This explanation is supported experimentally, in that when concomitant element precipitation is avoided through the use of more concentrated acid solutions (5 mol l<sup>-1</sup> HCl) and/or reduced concentration of tetrahydroborate reagent (0.5 versus 3%), the range of interference free determination can be enhanced 10–100 fold. Other theories suggest that, even in the absence of precipitation, signal suppression can occur due to the formation of a soluble complex between a lower than normal oxidation state of the interferent and the analyte. Excess NaBH<sub>4</sub> serves to stabilize this intermediate. In the presence of high concentrations of other hydride-forming elements, competitive reactions between the different hydrides and possible loss of compound on metal precipitates may occur.

Gas-phase interference effects have been noted due to the mutual interference from the presence of other hydride-forming elements. As above, the extent of the interference is only dependent on the concentration of the interferent and not on the analyte-to-interferent ratio. As atomization of the hydrides occurs by collisions with hydrogen radicals, a 'radical

population interference' may arise when an excess of cogenerated hydride depletes the hydrogen radical concentration to a level insufficient to completely atomize the analyte hydride. This theory is consistent with all observations made using heated quartz T-tube atomizers. Indeed, use of the multiple micro-flame quartz tube atomizer significantly reduces this problem, as noted earlier. Gas-phase interferences in the graphite furnace atomizer have been attributed to the formation of diatomic molecules between the analyte and cogenerated interferent and can be eliminated by use of high temperature.

A number of approaches have been taken to minimize or eliminate interferences. These include: increasing the acidity of the sample solution; reducing the concentration of the tetrahydroborate reagent; adding chelating or complexing agents to the solution (L-cysteine and L-cystine are particularly attractive); the addition of interference releasing elements such as iron, tellurium, and copper, and the preseparation of the analyte from the matrix.

FI techniques are particularly attractive for implementing such procedures, as they conveniently allow for rapid, elaborate sample pretreatment with minimal risk of increased contamination. This includes the online oxidation and prereduction of various chemical forms of the analyte, the addition of releasing or masking agents, as well as the separation of the analyte from major matrix components by ion exchange.

### Cold Vapor

No spectral interferences occur with the cold-vapor technique; water vapor does not absorb at the 253.7 nm line but water droplets carried into the cell may result in source attenuation. As a consequence, the cell is often operated at 200°C to prevent condensation.

Chemical interferences occur infrequently but include silver, arsenic, copper, iodine, antimony, and selenium. Tolerance to all these species except iodine and selenium is higher when  $\text{SnCl}_2$  is used as the reductant as compared to  $\text{NaBH}_4$ . Interference by platinum group metals using  $\text{NaBH}_4$  reductant is similar to that encountered with the hydride forming elements. Species containing sulfhydryl groups retard the release of mercury from the sample but this interference effect is eliminated with amalgamation and/or signal integration. Organomercury compounds can be conveniently preoxidized using  $\text{KBrO}_3$ - $\text{KBr}$ - $\text{HCl}$  reagent prior to tetrahydroborate reduction.

Partial or complete poisoning of the amalgamation trap is more likely to occur when  $\text{NaBH}_4$  is used as a reductant and the precautions outlined earlier are not

adhered to. Frequent cleaning in nitric acid minimizes this problem.

### Applications

Hydride generation techniques are superior to direct solution analysis in several ways. However, the attraction offered by enhanced detection limits is offset by the relatively few elements to which the technique can be applied, potential interferences, as well as limitations imposed on the sample preparation procedures in that strict adherence to valence states and chemical form must be maintained. Cold-vapor generation of mercury currently provides the most desirable means of quantitation of this element, although detection limits lower than AAS can be achieved when it is coupled to other means of detection (e.g., nondispersive atomic fluorescence or microwave induced plasma atomic emission spectrometry).

Applications of both vapor generation techniques have been widespread in that waters and effluents, metallurgical, clinical, biological, agricultural, geological, and environmental samples have all been analyzed at both the trace and ultratrace levels for these analytes. The reader is referred to the Further Reading section for an extensive compilation of specific applications.

Currently, detection power is primarily limited by reagent contamination. Progress in the widespread implementation of FI techniques, which feature online sample preparation and pretreatment capabilities as well as capabilities for rapid automation, should facilitate a further revolution in the use of vapor generation techniques in atomic spectroscopy.

## Introduction

Atomic (or optical) emission spectrometry (AES, OES) is an important technique for the multielement analysis of a wide range of materials. Many elements have been discovered using emission spectrometry and it is the most commonly used procedure for the measurement of trace elements in rocks, water, soil, manufactured goods, and biological specimens. The technique is used to monitor the levels of different chemicals and trace elements in the environment and to determine the compositions of solids, liquids, and gases. In geoanalysis, emission spectrometry has been instrumental in the exploration of economic mineral deposits. In metallurgy and in the semiconductor industry, emission

spectrometry is of prominent importance in the production control of both raw materials and finished products. Finally, emission spectrometry allows the elements present in the sun and stars to be identified, helping us to understand better the nature of the universe. These are only a few examples of scientific and technical disciplines in which the technique of emission spectrometry has made a significant contribution.

## Theory and Signal Generation

### Atomic Spectra

AES involves the measurement of electromagnetic radiation emitted from atoms. Both qualitative and quantitative data can be obtained from this type of analysis. In the former case, the identity of different elements reflects the spectral wavelengths that are produced, while in the latter case, the intensity of the emitted radiation is related to the concentration of each element. Atomic spectra are derived from the transition of electrons from one discrete electron orbital in an atom to another. These spectra can be understood in terms of the Bohr atomic model.

In the Bohr model, the atom is depicted as a nucleus surrounded by discrete electron orbits, each associated with energy of the order  $h\nu$ . Every atom has a certain number of electron orbitals, and each electron orbital has a particular energy level. When all the electrons are present in the orbitals, the atoms are in the most stable form (the ground state). When energy (either thermal, resulting from collision, or radiational, resulting from the absorption of electromagnetic radiation) is applied to an atom and is sufficient to lift an electron from a shell with energy  $E_i$  to one with  $E_j$ , the atom is said to be in the excited state. The state of excitation is unstable and decays rapidly. The residence time of the unstable excited state is very short, in the order of  $10^{-8}$  s. When electrons return to the stable ground state, energy is emitted and that energy is equal to the difference in the energies between the ground and excited states. The energy is released in the form of electromagnetic radiation and defines the wavelength of the transition. The relationship between the energy and wavelength is described by the Planck equation:

$$E_j - E_i = h\nu = hc/\lambda$$

where  $E_j - E_i$  is the energy difference between the two levels (and  $E_j > E_i$ );  $h$  is Planck's constant,  $6.624 \times 10^{-34}$  J s $^{-1}$ ;  $\nu$  is the frequency of the radiation;  $c$  is the velocity of light in a vacuum,  $2.9979 \times 10^8$  m s $^{-1}$ ; and  $\lambda$  is the wavelength of the radiation in meters.

If enough energy is absorbed by the atom, electrons may escape completely, leaving the atom in the ionized state. The energy required for ionization is called the ionization potential. Ions also possess ground and excited states, through which they can absorb and emit energy by the same processes described for an atom.

Figure 1 illustrates the electron shell configuration in terms of energy levels. Horizontal lines represent

energy levels and vertical lines depict permissible transitions between them. The arrows show the direction of energy input or output (ascending arrows show the absorption of energy while descending arrows show energy radiation). When an electron in a quantum level  $j$  is captured by an ionized atom, energy is liberated according to the following equation:

$$h\nu = h\nu_j + mv^2/2 = E_j + mv^2/2$$

The wavelength for the emitted radiation due to a transition  $E_j - E_i$  is

$$\lambda = hc/E$$

where  $E$  is the energy difference and  $\lambda$  is the wavelength of the emitted radiation.

Spectra of neutral excited atoms are denoted as I, and correspond to those deexciting to the ground state (resonance lines) or close to the ground state (near-resonance lines). They are observed in low-energy sources such as flames. Spectra of singly ionized atoms are denoted as II, and they are observed in high-energy sources such as electrical sparks, inductively coupled plasmas (ICPs), and glow discharges. Every element has a characteristic emission spectrum, which is the basis of spectrochemical analysis.

## Molecular Spectra

Molecular spectra consist of numerous densely grouped lines. These are called band spectra because they appear as luminous bands. The fine structure can only be observed with high-resolution instruments. Molecular spectra of excited molecules are related to the energy states of a molecule rotating around the principal axes of inertia. Band spectra in the near-infrared are produced by energy transitions related to oscillatory vibrations of individual molecules.

## Continuum

This is radiation distributed continuously over the wavelength range and can be attributed to recombination processes and other background factors. The intensity of the background increases with temperature.

## Instrument Design – Overview

A spectrometer consists of three main parts: (1) an emission source, which produces the spectrum; (2) an optical system, which scatters the spectrum; and (3) a device to measure the emitted lines. The two major types of instrument for the analysis of emission spectra are sequential and simultaneous spectrometers, although there are many variants of each in terms of mechanical and optical characteristics. The spectral

wavelength range of interest is  $\sim 160\text{--}900\text{ nm}$ , but not all instruments are capable of covering this range, and the resolution may vary with wavelength. Oxygen and water vapor absorb short-wave UV emissions ( $< 190\text{ nm}$ ) and this obscures the emission lines of some common and important elements (e.g., hydrogen, carbon, oxygen, nitrogen, chlorine, phosphorus, and sulfur). Therefore, oxygen and water vapor must be eliminated from the instrument, either by evacuation or by flushing with nitrogen or argon. Nitrogen flushing does not interfere with the analysis of samples containing nitrogen compounds since molecular nitrogen ( $\text{N}_2$ ) does not obscure the emission lines from atomic nitrogen in the sample.

## Instrument Design – Emission Sources

In spectrochemical analysis, atomization and excitation can be achieved using various different emission sources. The spectra derived from low-energy sources such as flames are simpler than those from electrical discharges, although the temperature of flames and furnaces ( $2000\text{--}4000\text{ K}$ ) is inadequate to excite many of the elements. Nevertheless, flame emission spectrometry is widely used for the determination of the alkali elements (lithium, sodium, and potassium), whose excitation states are low enough to be populated at flame temperatures. Higher-energy sources produce higher temperatures and therefore more emission lines. In electrical discharges, arcs and sparks are created by applying currents and potentials across conducting electrodes, and a large quantity of the sample surface is evaporated in this process. Better quantitative analysis is achieved using plasma sources: ICP, direct current plasma (DCP), and microwave induced plasma (MIP), which generally achieve temperatures of  $7000\text{--}8000\text{ K}$ . Glow discharge sources, which use high-energy argon atoms and ions to excite atoms ejected from the analyte surface, are often used for the analysis of metals.

The degree of excitation by a thermal source can be described by the Boltzmann distribution equation. If  $N_1$  is the number of atoms in the excited state and  $N_0$  is the number in the ground state, then the excited fraction is given by

$$N_1/N_0 = (g_1/g_0) \exp(-E/kT)$$

where  $E$  is the energy difference between the ground and excited states,  $T$  is the absolute temperature (K),  $k$  is the Boltzmann constant ( $1.38 \times 10^{-23} \text{ J K}^{-1}$ ), and  $g_1$  and  $g_0$  are quantum statistical weighting factors.

## Flame Sources

In flame emission spectrometry, the sample solution is sprayed or aspirated into a flame as a fine mist or aerosol. The sample is vaporized in the flame, and atomized by a combination of heat and the action of a reducing gas. The atoms are excited into higher electronic states by the heat, and as they revert to the ground state they emit photons, which are measured by the detector. The layout of a flame photometer is shown in Figure 2.

## Discharge Sources (Arcs and Sparks)

The first discharge sources produced direct current (DC) arcs by electrically heating the sample in an electrode cup and vaporizing the analytes into a low-voltage, high-current discharge. The temperature of the arc plasma varies from  $4000$  to  $5000\text{ K}$ . The limits of detection are good and the entire sample can be consumed. However, due to variations in the volatilization process, the accuracy is usually poor. Reproducibility can be improved by using internal references and optimizing the conditions of vaporization (graphite electrode designs, addition of modifiers). The spectral range of the source is limited due to the presence of cyanogen bands with heads at  $421.6$ ,  $388.3$ , and  $359.0\text{ nm}$  when graphite is used. Argon can be injected into the arc to minimize these effects. In the so-called cathode region, intensity is relatively higher ( $10\text{--}50$  times) than in the central and anode regions of the arc.

Spark sources produce lower average temperature than arcs, but the local temperature can be as high as  $40\,000\text{ K}$ . Like arc sources, sparks produce atomic lines, but also more pronounced lines for ions, which are known as spark lines. The emission source consists of a sparking stand and a spark generator. A spark forms between the cathode and the sample (which acts as the anode). The adjustable gap

**Figure 2** Schematic of a flame emission spectrophotometer.

between the cathode and the sample is sometimes termed the entrode, and is filled with argon. The generator initially produces a brief low-energy discharge that ionizes the argon and creates the plasma. A second, high-energy discharge then causes the sample to vaporize at the sparking point, exciting the atoms and generating the emission spectrum. A large number of sparks is generated, each lasting only a few microseconds. Due to the lower sample consumption, the limits of detections are poorer than in the arc. The high-voltage alternating current (AC) arc is intermediate in analytical performance between the DC arc and the high-voltage spark. These sources are used mainly in the metallurgical industry.

### Direct Current Plasmas

The DCP evolved from DC arcs and can be classified into two types: discharges confined within a chamber (wall-stabilized) and unconfined plasmas. Various designs and configurations of the electrode exist for injecting the sample aerosol-carried gas into the plume, one of which is shown in **Figure 3**. Magnetic fields can be used to enhance the coupling of the sample into the plasma, as is useful for the analysis of very complex materials. It is characterized by ease of operation, robustness, and optimization for a great variety of complex matrices. Analyte signals are observed in the tail flame or close to the region where the sample is injected into the discharge and where the density of excited species is greatest. The discharge has been shown to be suitable for the analysis of slurries and solutions containing very high salt concentrations.

### Microwave-Induced Plasmas

MIPs have been used widely in gas chromatography (GC) detection. Low-power MIPs (50–150 W) do not accept liquid aerosols efficiently. One way of overcoming this disadvantage is to desolvate the sample solution or to employ electrothermal vaporization. A commercial system is available consisting of a

water-cooled discharge tube inserted in a reentrant-type cavity that does not require tuning. It is generally considered that a laminar flow torch is more suitable than tangential flow for GC detection. In its usual form, the MIP operates with a low helium flow rate ( $1 \text{ l min}^{-1}$ ). MIPs are very suitable for the determination of halides and other nonmetals. A microwave plasma torch (MPT) has been developed consisting of concentric copper tubes. The carrier gas and aerosol enter the inner tube while the outer tube serves as the microwave cavity. The plasma is formed at the top of the MPT and extends out like a flame, but with a central channel for the introduction of the aerosol. The MPT is superior to the conventional MIP since it allows the introduction of wet aerosols at lower power.

### Inductively Coupled Plasmas

ICP sources have brought about a revolution in multi-element analysis. ICPs are generated from radiofrequency (RF) magnetic fields induced by a water- or air-cooled copper coil looped around a quartz tube. The RF magnetic field oscillates at 27.12 or 40.68 MHz, at incident powers ranging from 0.5 to 2.5 kW. Higher powers are usually applied when organic solvents are aspirated. Argon gas flows through a torch, which consists of three concentric tubes usually constructed from fused silica. The plasma is initiated by seeding the argon stream with electrons provided from a Tesla coil. The electrons, detached from the argon atoms, collide with further argon atoms and populate the coil region with positive and negative charges. Because of the magnetic field, the particles flow in a closed annular path. Due to the conductance of the gases in the coil region, the charged particles are heated by inductive coupling to a temperature equaling the ionization temperature of the support gases  $\sim 7000\text{--}8000 \text{ K}$  in the case of argon. A chain reaction of collisional ionization occurs, resulting in the formation of the ICP. In practice, the plasma impedance is monitored along with the tube grid current, grid voltage, plate current, and voltage. These data are fed back to a loop to control the plasma power. The configuration of an ICP-AES system is shown in **Figure 4**.

### Glow Discharge Sources

Glow discharge is based on a phenomenon called sputtering, where atoms ejected from the surface of the analyte by high-energy argon atoms and ions achieve the excited state in the resulting plasma. A copper tube filled with argon is juxtaposed with the sample and a potential difference applied across the gap, with either a direct current or a RF alternating current. Electrons jump from the negatively charged

**Figure 3** A schematic design of a direct current plasma source.

sample toward the positively charged copper electrode and collide with argon atoms, creating positively charged argon ions that are attracted toward the sample surface. En route, they collide with other

argon atoms and ions, and then strike the analyte surface with sufficient energy to displace electrons and atoms from the sample (sputtering). These analyte atoms also collide with the electrons and high-energy argon atoms/ions, causing them to be excited to higher energy states. As they deexcite, they emit photons resulting in a 'glow' extending 2–3 mm from the sample (Figure 5).

Glow discharge sources are based on three principal designs. The Grimm source, which consists of a copper cathode block in direct contact with the metal sample, is used with DC voltage. The Renault source is based on the Grimm source, but utilizes a ceramic cathode block that allows the use of RF voltages. The most recent development is the Marcus source, which also operates in RF mode. It has a ceramic cathode block and a very short anode tube to facilitate rapid plasma expansion. Although DC and RF plasmas are similar, RF plasmas are more stable and show a greater sputtering depth. The most important difference is that RF glow discharges can be used to analyze both conducting and nonconducting analytes, while DC glow discharges are restricted to conductors.

**Figure 4** Schematic of an inductively coupled plasma source for atomic emission spectrometry.

## Instrument Design – Sample Introduction

Some of the emission sources discussed above are designed for use with solid samples, which can be

**Figure 5** Principle of glow discharge atomic emission spectrometry.  $D$  = diameter of the anode and  $d$  = distance from anode to sample.

attached to or used as electrodes. For plasma sources, solid samples can be converted into slurries if the particle size is small, but an alternative is to use spark ablation or laser ablation to explode the sample, generating a small amount of vapor that is carried into the plasma in a gas stream. Gaseous samples can be analyzed directly, but liquid samples are first converted into aerosols, so that they can desolvate and atomize completely. The most common sample delivery system consists of a peristaltic pump and capillary tube to deliver a constant flow of analyte liquid into a nebulizer. The nebulizer turns the analyte liquid into fine droplets, which are carried by gas into the plasma. Larger droplets ( $> 5 \mu\text{m}$ ) are captured in the spray chamber, and are drained from the instrument.

### Analysis of Solids in Plasma Sources

**Spark ablation** In this method, conducting samples are vaporized with an electrical discharge, while nonconducting samples are first modified by mixing with copper or carbon powder. The dry aerosol is carried by an argon stream into the plasma. The system is calibrated with samples of similar physical and chemical composition. Slight differences can be compensated through the use of internal standards. Large particles can be eliminated using traps, as long as internal references are available.

**Laser ablation** This method is used as a micro-chemical sampling procedure for localized determinations. A pulsed neodymium–yttrium aluminum garnet (Nd–YAG) laser is used to ablate material from solid samples. Repetitive laser pulses and sample translation can be used to improve the precision and accuracy of the analysis. Refractory materials and geological samples can be analyzed for trace and major elements. Powdered samples can be pelleted under high pressure for bulk analysis.

### Nebulizers

Many different types of nebulizer are available, some of which are suitable for general analytical purposes while others have more specialized uses. Pneumatic nebulizers are general-purpose devices in which the aerosol is formed by the shattering effect of a high-velocity jet of gas. The most commonly used pneumatic nebulizer is the Meinhard glass concentric nebulizer, in which the sample is introduced along a narrow capillary tube located within a larger glass or quartz tube. The outer tube contains argon gas, which flows to a 10–20 mm gap surrounding the sample capillary. The aerosol is formed by the

venturi effect produced by the gas stream as it is forced through the annulus, which fragments the liquid into fine droplets. The Meinhard nebulizer is sensitive to clogging, so particulates and solutions with high salt concentrations should be avoided.

Cross-flow nebulizers consist of a capillary tube that directs a stream of argon gas at  $90^\circ$  to the sample delivery tube, creating an aerosol due to its shearing effect over the sample tube. Again, these nebulizers are designed for general-purpose use, although they are less prone to blockage where the sample has a high salt concentration. Parallel flow nebulizers, such as the Burgener nebulizer, consist of parallel sample and gas capillaries with adjacent exits, so that the liquid sample is drawn into the gas stream. These are designed specifically to deal with inert samples with a high concentration of dissolved solids. In the Babington nebulizer, the liquid sample flows over a smooth surface containing a small orifice, through which argon flows at a high velocity, shearing the liquid into tiny droplets. As above, this device is not susceptible to clogging and can handle viscous solutions and suspensions. Another nebulizer designed for these difficult samples is the V-groove nebulizer, a special type of Babington nebulizer in which the liquid flows down a vertical V-shaped groove toward the gas orifice, from which argon flows at a pressure of 210–1050 kPa. A further Babington-type nebulizer, the Frit nebulizer, produces very fine aerosols but has very long washout times.

Ultrasonic nebulizers offer enhanced sensitivity in detection limits by using a vibrating piezoelectric transducer to set up standing waves in the liquid to produce uniformly sized droplets. The efficiency of nebulization is so high that the solvent loading of the aerosol needs to be reduced by thermal desolvation, otherwise cooling of the plasma takes place. Direct injection nebulizers (DINs) are effective devices for introducing liquids directly into the plasma when flows are slower than  $0.1 \text{ ml min}^{-1}$ . By avoiding the use of a spray chamber, DINs allow 100% transport into the plasma. However, solvent loading in the plasma can exceed the optimum level and can cause a reduction in the plasma temperature, resulting in lower intensities.

### Instrument Design – Optical Systems

Once the sample has been introduced into the emission source, atomized, and excited, the emitted photons are diffracted by an optical system consisting of slits, mirrors, and gratings, which focus the spectral lines onto a detector. This section discusses the types of gratings and spectrophotometer designs that can be used in AES.

## Gratings

Gratings are reflective surfaces containing parallel, equally spaced lines. Their resolving power is proportional to the number of lines, which in turn depends on the line spacing. For radiation arriving with an angle of incidence  $\alpha$ , the angle  $\beta$  at which it will be diffracted by a grating of  $N$  lines per millimeter depends on the wavelength  $\lambda$  of the radiation, and is defined by the equation

$$\sin \alpha + \sin \beta = kN\lambda$$

In this equation,  $k$  is the order of diffraction, meaning that constructive interference occurs at wavelength  $\lambda$  (first order),  $\lambda/2$  (second order),  $\lambda/3$  (third order), and so on. The spectrum produced by a grating thus consists of several superimposed orders, with the first and second orders carrying most of the energy. The blaze angle of a diffraction grating is the mirroring angle of each line. The blaze angle is not arbitrarily selected; radiation can be concentrated into the first order, rather than in multiple orders and the performance of the grating for a particular spectral range can be optimized by varying the blaze angle. To cover the entire analytical spectral range, two gratings may be employed, or the spectra can be observed in several orders.

Ruled gratings have been replaced by holographic gratings produced from the interference patterns generated by two synchronous lasers. The interference pattern is etched into a photosensitive film, and replicas of these gratings can be manufactured readily. The grating pattern created in this way is greatly superior to those produced mechanically, being much more accurate, having higher linearity, and being free from imperfections and distortions that can give rise to ghosts and stray light. However, the brightness achieved by the conventional holographic gratings is not as high as that of ruled gratings because of the sinusoidal groove profile.

The echelle grating is designed to operate in multiple orders to produce high-resolution spectra. In contrast to normal gratings, echelles are ruled at 30–300 grooves per millimeter by ion bombardment, and are frequently in the range of 30–120 orders. The grating consists of saw-like grooves varying in height and 6–13  $\mu\text{m}$  in depth. The echelle grating is designed to separate one order of diffraction from another. This is achieved by inserting a quartz prism, which acts as an order sorter, in front of the grating. Successive spectra are diffracted to different degrees, so that the various orders appear as a two-dimensional array of wavelengths. These gratings are installed in polychromators, sequential systems, and in charge-injected and charge-transfer detector instruments (see below).

The resolving power of a grating is a measure of its ability to separate to the baseline two adjacent spectral wavelengths  $\lambda_1$  and  $\lambda_2$ . The resolution  $R$  is expressed as

$$R = \lambda/(\lambda_1 - \lambda_2)$$

## Monochromators

A monochromator measures a single wavelength, but can be scanned through a wide wavelength range. Polychromatic light passes through an entrance slit and is dispersed by diffraction gratings. These instruments are used in sequential mode, element determinations being performed one after the other. Two designs are usually employed in commercial instrumentation: Czerny–Turner and echelle.

**Czerny–Turner monochromators** Two mirrors are used to reflect and focus the polychromatic and diffracted beams. Wavelengths are selected by using a computer to rotate the grating in various ways. This design is shown in Figure 6. As the grating rotates, a different wavelength is focused onto the exit slit.

**Echelle monochromators** These are high-resolution instruments that readily achieve resolutions of 5 pm in contrast to the 10–20 pm that is normal for conventional sequential instruments. Because the spectra are recorded one above the other, such instruments can be very compact.

## Simultaneous Spectrometers

There are several types of simultaneous instruments, which carry out elemental determinations in parallel rather than in series. They differ in optical design and the type of detector that is used.

**Polychromators** These instruments can measure numerous spectral lines simultaneously, and several approaches can be used to achieve this. In the classical Paschen–Runge design, light is directed onto a diffraction grating that diffracts the polychromatic radiation into its individual wavelengths. Exit slits are located at predetermined positions on a Rowland circle to focus the diffracted wavelengths onto a specific photomultiplier tube (PMT). In this design, the number of elements that can be determined simultaneously is limited by the geometric configuration of the exit optic area of the instrument. This is a disadvantage compared with the state-of-the-art charge-coupled and charge-injection devices discussed below. Geometric alignment is also controlled by the space requirements of the PMTs, and as a

**Figure 6** Czerny–Turner monochromator. ICP = inductively coupled plasma and PMT = photomultiplier tube. Reproduced from [www.thespectroscopynet.com](http://www.thespectroscopynet.com)

result a series of mirrors is employed to direct the spectral radiation to the measuring surface of the detector. For the determination of the spectral lines in the low part of the UV spectrum ( $<190$  nm), as is necessary in the detection of aluminum and phosphorus, the spectrometer must be contained in a vacuum or purged of oxygen using nitrogen or argon gas.

Polychromators have several advantages, including high sample throughput, lower running costs, and the ability to measure more than 20 elements, in duplicate, with background correction in less than 5 min using only 5 ml of solution. However, disadvantages include the high costs associated with the individual electronic systems required for each spectral line measurement, and the inflexibility of the instrument due to the static optical system.

## Instrument Design – Detection

### Photomultiplier Tubes

Photons emerging from the exit slits of the spectrophotometer are detected by one of two types of device, a PMT or a solid-state component. Photomultipliers are often used as detectors in AES. Incident photons emerging from the exit slit fall on the photocathode, liberating electrons, and the current is amplified by a set of dynodes. The final anode current is proportional to the incident photon signal received by the photocathode. The measurement dynamic range is very broad, i.e.,  $10^{15}$ , and sensitivity is high. These detectors allow the detection of low intensities emitted by trace elements, as well as strong signals from major elements. They have very fast response times,

typically 1–2 ns for a 10–90% change in signal. The main inconvenience of photomultipliers is their cost.

There are several types of photomultipliers, which differ in the nature of the entrance window, either crystal or fluoride, and in the nature of the sensitive layer on the photocathode. Some are only sensitive in the far-UV while others are more sensitive in the visible. The type of photomultiplier to be used is selected according to the wavelength of the line to be detected. A fatigue lamp (a small incandescent light source) is often used with photomultipliers to keep the temperature of the tube and its associated electronics constant. The fatigue lamp is switched on when the emission source is off and vice versa.

**Charge-injection devices (CIDs)** CIDs can be used in combination with an echelle spectrometer to produce a flexible detection system for multielement analysis using a direct current arc, AC spark, or inductively coupled or direct current argon plasmas. The CID consists of a two-dimensional array of detector elements and when it is coupled to a polychromatic dispersive system, simultaneous multielement analysis is provided over the spectral range 170–800 nm. In addition to the multielement capability and large dynamic range (eight orders of magnitude), the system allows random access integration, where each detector element can be nondestructively processed until an appropriate signal-to-noise ratio is attained. Background can be read simultaneously, and alternate spectral lines can be selected for the analysis of spectrally complex materials. The detection limits are similar to those obtained by conventional

detection systems. The system is ideally suited to semiquantitative screening analysis.

**Charge coupled devices (CCDs) and echelle polychromators** CCDs and echelle polychromators are now available, and in such systems the high-energy echelle spectrometer utilizes two detector focal planes and two cross-dispersers. At 200 nm, the resolution is 0.007 nm but this degrades substantially in the visible region. The cross-disperser for the UV region (167–375 nm) is a grating (374 lines per millimeter) with a Schmidt correction incorporated into its surface. Aberration is also corrected for a 400 mm radius focal plane. The cross-disperser for the visible region is a fused 60° quartz prism. A segmented array CCD consists of 224 addressable subarrays with over 6000 pixels on a 13 × 18 mm silicon substrate. One of the drawbacks of the CCD is the inability to read nondestructively. When the charge is read on a subarray, it is destroyed and cannot be monitored to adjust the integration time.

**Photodiode arrays (PDAs)** A spectrally segmented PDA spectrophotometer has also been developed. Radiation from the plasma is predispersed and transmitted through an optical mask prior to dispersion by an echelle grating onto a PDA. Limits of detection are similar to those obtained by conventional detection systems, except at low wavelengths where degradation has been observed.

## Interferences and Background Correction

**R M Twyman**, University of York, York, UK

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

When a spectral line produced by one element is very close to a line produced by another element, interference between the two lines may take place. If this

happens, the measured intensity is a combination of the intensities of the two emission lines and does not give a true indication of the abundance of either element. Spectral line interference in atomic emission spectrometry (AES) can severely affect the accuracy of trace and minor element determinations. Therefore, measurement of the analytical line of interest must take into account the possibility of interference from adjacent spectral lines and the interference

should be corrected to obtain the true intensity of the element being measured. The level of interference is dependent upon the composition of the sample, the gases used in the instrument, and the resolution of the spectrometer. Carry-over, contaminated reagents, and matrix interference effects may also occur. Interference becomes worse as the concentration of the interfering element in the sample increases and as the resolution of the instrument decreases. There are several different forms of interference, including the background continuum, stray light, wing overlap, molecular bands, and direct overlap. Table 1 shows examples of interference types commonly observed when using inductively coupled plasma (ICP) sources.

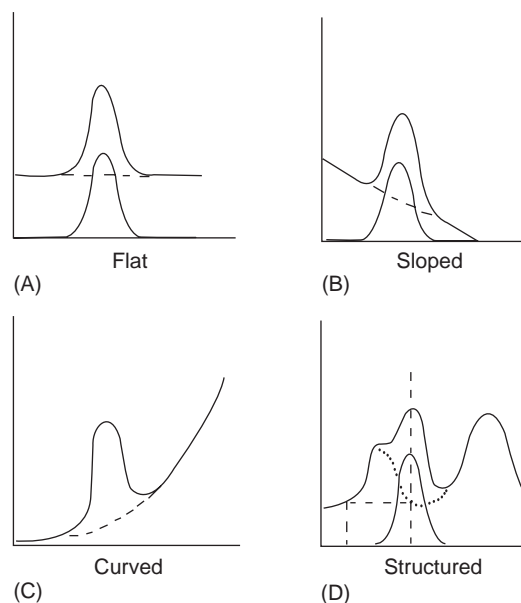

## Types of Spectral Interference

### Background Continuum

The background continuum is radiation distributed continuously over the wavelength range of the spectrometer. This type of interference originates from several sources, including recombination, Brehmsstrahlung, line-broadening, stray light within the spectrometer, and the presence of molecular species. Its intensity increases with temperature. Several typical forms of background are shown in Figure 1.

A common source of background is the support gas plasma. The effect is minimal with air and nitrogen but very intense when argon is used. About 200 argon lines have been observed predominantly between 350 and 450 nm (there appear to be none in the ultraviolet (UV) range). Very intense and broad argon lines are produced in the near-infrared range

when ICP sources are used, limiting the applicability of this technique in the detection of halides and other nonmetals. Where the analyte is dissolved in an organic solvent, further interference occurs in the form of intense carbon lines.

**Figure 1** Types of background emission in atomic emission spectrometry. (A) Flat background, which can be addressed using one-point correction. (B) Linear sloping background, which can be addressed using three-point correction. (C) Curved background, still with continual variation. This is best addressed using multivariate techniques. (D) Complex, structured background, comprising interferences from line-rich elements. May be overcome with higher resolution analysis although multivariate statistical techniques such as Kalman filtering can also be applied (see main text).

**Table 1** Examples of interference types in analytical ICP-AES

Type of interference	Interferent	Analyte	Application
Spectral overlap	Ca 180.74 Mn 180.747	S I 180.73 S I 180.73	Sulfate in water
Spectral overlap	Ti 228.618	Co II 228.616	Co in Ti alloys and rocks
Spectral overlap	Cu 213.853	Zn 213.856	Zn in Cu alloys
Spectral overlap	Fe II 234.8	Be 234.861	Be in geological materials
Spectral overlap	Be II 313.042	Ti II 313.08	
Resonance broadening	Ca 393.3 Ca 396.8	Al 396.1	Al in drinking water and serum
Far scatter	Ca 393.37	Zn I 213.68	Zn in drinking water
OH bands	OH 310.327 OH 310.236 OH 310.214 OH 310.123	V II 310.23	Trace determination of V
OH bands	OH bands	Be II 313	
Cross-talk	Mg 279.5	Cr 267	
Broadening	Wings Al 214.54	Al 220.467 Cd II 214.438	Pb II 220.353 in geological samples
Carbon lines	C 193.09	As 193.7	
C2 Mullikan system	232.5	Ni 231.604	

Recombination (the capture of electrons by ions) is another source of background, and while the continuum is present throughout the optical range of the spectrometer, it increases with decreasing wavelength and is most troublesome at  $\sim 200$  nm. The light emitted by aluminum in the range 190–220 nm is due to recombination, and this interferes with numerous of other elements in the same region of the spectrum. In ICP-AES, background enhancements for calcium, magnesium, and aluminum can seriously affect analytical performance, and in the case of aluminum this is due to the broadening of the most intense lines.

As the sensitivity of detection approaches the limit of the spectrometer, noise factors in the instrument should also be taken into account. Sources of noise influencing the signal-to-noise ratio in ICP-AES have been published extensively, and include fluctuations in the nebulizer-spray chamber system, plasma flicker, and pulsation. In high-voltage spark dischargers, the light emitted during the first 5–10  $\mu$ s consists primarily of continuum and band spectra that fade, while the emissions of analyte spark lines persist for  $\sim 50$   $\mu$ s. Therefore, the time resolution can be used to distinguish genuine signals from background.

### Stray Light

Stray light is radiation inside the spectrometer that has a wavelength outside the spectral band pass. It arises mostly due to imperfections in the optical design of the instrument, and its impact has been reduced as instruments have evolved and become more sophisticated. The magnitude of the effect is sample-dependent, and is particularly noticeable when solutions containing high concentrations of calcium and magnesium are analyzed. There is evidence that stray light is derived from the strong Ca II 393.366 and 396.847 nm lines, and that the limits of determination of aluminum in calcium-rich solutions are degraded unless holographic gratings are used.

Cross-talk is the interception of unwanted light in the region of the slit and photomultiplier tube (PMT). This occurs when the radiation from a strong emitter falls upon the slits, mirrors, and detectors of adjacent analytes. For example, if the detector system for the Cr 267.716 nm line is located next to the very intense Mg 279.553 nm line in the focal plane, cross-talk can occur if detection optics have not been adequately masked.

### Line-Broadening and Wing Interference

The broadening of spectral lines can be due to Doppler effects, foreign gas, or resonance effects. Doppler broadening is due to the random motion of atoms. The atoms move in different directions and

at slightly different speeds, so individual atoms emit light at slightly different wavelengths depending on whether they are moving toward or away from the detector. Doppler widths can be in the order of 0.001–0.01 nm, depending on the element. Doppler broadening produces a Gaussian profile, and the wing intensities decrease rapidly, therefore contributing nothing to the background more than 0.01 nm away from the broadened spectral line.

Foreign gas broadening is due to collisions between unlike atoms, and includes a related phenomenon called Stark broadening which is caused by collisions between excited atoms and charged particles, i.e., electrons and ions. Collisions between atoms and other particles cause the energy levels in the atoms to change, and thus the energy required to excite the atoms also changes by a small amount. At 5000–6000 K, the effect of foreign gas broadening is even smaller than that of Doppler broadening, and usually can be ignored.

Resonance broadening is caused by collisions between like atoms, and this has a significant impact on wing intensities because its effect is to broaden the wings and suppress the central emission line. The effect occurs because, at higher pressures where atoms are closer together, photons emitted at the peak frequency are likely to be absorbed by surrounding atoms, while those at the wings are less likely to be emitted and trapped by surrounding atoms. As an example, resonance broadening of the Ca I 393.3 nm and Ca II 396.8 nm lines results in interference with the 396.1 and 394.4 nm lines of aluminum, such that the limits of detection for aluminum are degraded in the presence of high concentrations of calcium.

### Molecular Bands

Molecular bands occur due to the energy states of a molecule rotating around the principal axes of inertia and the energy transitions related to oscillatory vibrations of individual molecules. Examples of molecular bands interfering with atomic lines include the hydroxyl radical and organic compounds. Hydroxyl radicals are produced both in dry plasmas (from the entrainment of hydrogen and oxygen) and in wet plasmas (from the dissociation of water molecules). Rotational spectra are produced in the 281–295 and 306–325 nm ranges.

Significant carbon-based molecular bands have been identified when samples containing high concentrations of carbon are excited. The C2 Swan bands are located at 593–620, 527–547, and 467–474 nm. The Mullikan C2 system occurs at 232.5 nm and degrades the limits of detection of lines such as Ni 231.604 nm. Bands due to cyanogen (CN) are

predominant in direct current (DC) arcs where nitrogen is entrained in the arc column. These molecular bands can be reduced by adding oxygen to the plasma (ICP sources) or argon in the case of DC arcs. As a result, the limits of detection are improved, especially for the rare earth elements in DC arc sources.

### Direct Spectral Overlap

Elements such as tungsten, zirconium, uranium, and the rare earth elements have multiple spectral lines, which make line selection a difficult task. The degree of interference and sample composition is related to what is called the critical concentration ratio (CCR), which is defined as the ratio of the concentration of interferent  $i$  to that of the analyte  $a$  at which the ratio of the line intensities  $I_i/I_a$  is equal to unity. If the measured concentration ratio exceeds the CCR, the intensity of the interferent line will be higher than that of the analyte line and will be detrimental to accuracy. In some spectrometers, optical cross-talk in the region of the exit slit and detector will present itself as a direct overlap.

## Techniques to Correct for Spectral Interferences

### Line Selection

In classical emission spectrometry, there are numerous listings of spectral lines. The Massachusetts Institute of Technology (MIT) Wavelength Tables list 110 000 spectral lines, and the intensities quoted are those observed in DC arcs or alternating current (AC) sparks. The National Institute of Standards and Technology (NIST) Atomic Spectra Database contains ~72 000 spectral lines with intensities observed in a copper arc. The database is accessible over the Internet ([http://physics.nist.gov/cgi-bin/AtData/main\\_asd](http://physics.nist.gov/cgi-bin/AtData/main_asd)) and can be searched using either lines or energy levels. The values of the upper and lower energy transitions are listed. Other lists are available for spectral lines located in the vacuum UV.

Although the relative intensities of spectral lines in the ICP differ from those observed in the DC arc and AC spark, the published tables are invaluable for the selection of analyte lines in ICP sources, and the identification of spectral interferences in the spectrometer bandwidths. However, spectral lines are emitted by ICP sources that are not emitted by DC arcs and sparks. In order to facilitate spectral line selection in ICP-AES, numerous spectral line atlases are now available which list the best analytical lines and the potential interferences due to coincidences from major and minor constituents. Simulated

interference allows spectral lines to be selected for various materials.

### High-Resolution Spectrometers

Direct line interferences can only be avoided by selecting alternative lines, or performing a line interference correction. The interference from adjacent lines can be minimized by using high-resolution spectrometers, decreasing the width of the slits or using higher spectral orders. A high-resolution spectrometer is a definite advantage for the analysis of spectrally complex materials. However, there is a practical limit to the resolution that can be achieved. This is determined by the natural line widths and the extent of broadening. Furthermore, even with a high-resolution monochromator, there may not be sensitive lines free from spectral interferences that can be used for trace element determinations in complex materials.

### Background Correction

Background correction is used to compensate for continuum interferences. In the simplest cases (where the background is static across the spectral wavelengths of interest, as shown in **Figure 1A**), this can be performed by measuring the background at a single point and subtracting the intensity from the gross signal to derive the analyte concentration. This one-point background correction method also facilitates the measurement of the background when there are sample-to-sample variations in background levels. The nature of the background can be determined rapidly by scanning a representative sample, reference materials, or synthetically prepared solutions and solids in the region of the analyte line.

Background effects are rarely as simple as discussed above. In **Figure 1B**, the background is not constant, but declines with increasing wavelength. Such a situation could occur when the analyte line is close to a broadened interferent. In this case, the use of a single point would produce an erroneous result and two points at approximately equal distances from the center of the profile should be used to calculate the background. Since one signal is measured at the analyte line and two signals are measured in the adjacent wavelengths to determine the background, this is called three-point background correction. The average of these measurements, or their weighted average if unequal distances are used, is subtracted from the peak intensity.

The case shown in **Figure 1C** is a variant of **Figure 1B** where the background shows a curved rather than sloping profile, and the procedure described above would produce only an approximate correction.

However, the collection of multiple readings across a spectral window centered on the analyte wavelength allows correlation or digital filtering methods to be used. These transform the data and fit the curve to a mathematical function, which can be applied to the unimproved spectrograph and used to eliminate the smoothly varying background. Heuristic and statistical algorithms have been used in this manner, as well as convolution methods, e.g., square wave convolution using a zero area symmetrical one-period square wave.

In Figure 1D, background compensation in the vicinity of the analyte line is difficult because the background is structured. This type of interference can only be overcome with a high-resolution spectrophotometer or with a multivariate convolution technique. When photodiode arrays or solid-state devices such as charge coupled devices (CCDs) and charge injection devices (CIDs) are used, it is possible to measure the background at the same time as the analyte. Separate channels are used for the selection of analyte spectral lines and regions for background comparison. Background can also be reduced by adjusting the operating conditions of the source to enhance the signal-to-background ratio. For example, in DC arcs the background can be reduced by operating the plasma in an inert argon atmosphere. In ICP sources, the use of a 40.68 MHz generator results in significantly lower background due to the reduced temperatures.

### Spectral Line Interference Coefficients

The contribution of interference elements can be estimated by performing spectral line interference corrections. Calibrators are prepared in which mutually interferent elements are not present in the same solution. These solutions are then used to calibrate the system. Apparent concentrations are obtained by analyzing the ultrapure single element solutions (or solids). The interference coefficients are calculated by dividing the apparent concentration by the concentration of the interferent. In ICP-AES, the corrections are generally linear and thus a single element solution suffices to determine the correction factor. In spark and DC arc emission spectrometry, several samples are required. In practice, the determination of an element may be influenced by several other sample concomitants, and the final corrected concentration must be the summation of all the interferents. To complicate matters further, an iterative procedure must be used to deal with mutual interferences.

It should be emphasized that correction coefficients can vary as a function of ICP operating conditions.

A spectroscopic diagnostic has been developed to maintain the optimum conditions of ICP operation, in particular the flow rates of the aerosol carrier. The ratio between an atomic line of copper and an ion line of manganese is used to adjust divergent intensity responses because of unfavorable operating conditions. When this diagnostic is applied, the variability of the interference coefficients is small. The larger the correction factor, the larger the error in the quantitation of the analyte line subject to interference.

### Multivariate Procedures

Mathematical procedures have been developed to automatically extract the analyte line from a structured background comprising continuum, instrument drift, and line interferences. Convolution techniques and Fourier deconvolution can be used to recognize individual peaks and resolve analyte and interference lines by width reduction, often resulting in two- to three-fold improvements in resolution. However, the greatest impact has been made by the use of multivariate statistical methods, including Kalman filtering, multiple linear regression (MLR), partial least squares (PLS) analysis, the generalized standard additions method (GSAM) and methods for pre-reducing the number of spectral lines used. Such methods have been shown to correct for spectral line interferences separated by as little as 1–2 pm from the analyte line, even using a medium resolution spectrometer. Analyte/interferent intensity ratios are as low as 1:10 and the analyte intensity is close to the limit of detection. Kalman filtering also corrects for the noise adjacent to the line, corrects for spectral drift, calculates the concentration of unknowns, and compensates for spectral line interferences if the lines of interferents do not overlap. Since the noise averaged over the spectral window and peak area is used rather than height, true limits of detection in the sample are between one and three orders of magnitude better than conventional limits of detection obtained using three-point background compensations. All these techniques are based on the recognition of the spectral forms, i.e., a complete model of the spectral interferences has to be made. Therefore, the system requires the scanning of the sample and pure component solutions of the analytes and the interferences in the bandwidths of interest. Thus, a large amount of work is needed in order to identify the interference in individual scans before the technique can be applied.

## Introduction

The history of spectroscopy is closely associated with the use of flames as light sources from its beginnings more than two hundred years ago. Qualitative analyses for several elements were being carried out over the last one hundred years. Quantitative analyses evolved in the 1930s as spectrometers and light-measuring devices were improved. The peak of interest in flame emission was reached in about 1960. Thereafter atomic absorption took over much of the field: absorption measurements are easier to perform, and the range of elements that can be determined is broader. The somewhat more complex instrumentation needed was quickly put in reliable form. Graphite furnace methods extended the range of usefulness of atomic absorption. More recently, high-energy plasmas with very sophisticated instrumentation have further replaced flame emission. In this article the basic processes of flame emission will be described and the range of its usefulness re-examined. It is suggested that modern developments make it a useful method still.

## Signal Generation

Compared with other common excitation sources – the arcs, sparks, and plasmas – flames have rather

low temperatures, up to 3000 K. Most atomic transitions thus occur between the ground state and a few low-lying excited states, even with elements having great numbers of possible states.

The temperatures of several common analytically useful flames are given in **Table 1**. These are the so-called theoretical temperatures, calculated for stoichiometric fuel–oxidant gas mixtures by Snelleman. They are roughly one hundred degrees higher than most measured temperatures. Moreover, the stoichiometric mixtures do not give the highest attainable temperatures: these are reached at somewhat higher fuel-to-oxidant ratios, especially for the air–acetylene flame, due at least in part to air entrainment. Fuel richness also alters rates and extents of chemical reactions in flames. In any case, the tabulated values show the relative temperatures of useful flames.

The distribution of atoms of an element among available states of energy  $\varepsilon_i$  above the ground state is governed by their energy and the absolute temperature according to the familiar Boltzmann factor,  $\exp(-\Delta\varepsilon_i/kT)$ . The most intense lines, often called

600	$6.27 \times 10^{-6}$	$3.39 \times 10^{-4}$
700	$3.46 \times 10^{-5}$	$1.06 \times 10^{-3}$
800	$1.25 \times 10^{-4}$	$2.50 \times 10^{-3}$
900	$3.39 \times 10^{-4}$	$4.8 \times 10^{-3}$

resonance lines, are those arising from permitted transitions between the ground states and certain low-energy excited states. Values of the factors are given for 2000 K and 3000 K, the useful flame temperature range, at intervals throughout the spectrum (Table 2). When corrected for their multiplicity (small whole number factors), the values give the fractions in the excited states directly. It is apparent that the vast majority of atoms in flames are in their ground states.

These considerations have several practical results.

1. Flame atomic absorption is more sensitive for those elements having their resonance lines at shorter wavelengths. (However, the line from the primary light source, the hollow cathode lamp, must also be sufficiently intense, a condition that is now readily attained.)
2. In hotter flames, elements having resonance lines at longer wavelengths may show greater sensitivity (lower detection limits) by emission than by atomic absorption. In an absorption measurement, one must always measure the difference between the incident and transmitted intensities: the detection limit is reached when the difference approaches the combined variations in these two intensities. Flame emission has no such restraint.
3. Flame emission spectra are relatively simple, and small spectrometers were thus considered adequate. The more versatile and larger modern instruments have greater resolving power so that more spectral lines are resolved and background continuum is made weaker by their greater dispersion.
4. Flame-burning velocities (Table 1) determine the minimum gas flow rates needed to keep the flame burning smoothly above the burner slot. The 'residence time', during which a given atom passes through the observed flame region, is thereby established –  $\sim 1$  ms in common flames. The slower-burning nitrous oxide–acetylene (NOA) flame is thus

preferred to the hotter but much faster-burning oxy-acetylene flame, which is also inclined to explode.

5. Excited species may be produced by mechanisms other than thermal excitation, e.g. chemiluminescence, so that the intensity is greatly increased.

## Atom Formation

Samples generally are introduced into flames in the form of solutions, by spraying or 'nebulizing' either directly into the flame along with the fuel or indirectly into a chamber to allow coarser droplets to settle out, with the finer aerosol and fuel passing on to the burner. The direct 'total consumption' approach was widely used in emission until the advent of atomic absorption, for which it was less suitable. It was turbulent, audibly noisy, and gave less complete vaporization of solutes. This type of sample introduction is still used in some clinical flame photometers.

The indirect 'premixed' nebulizer–burner combination is inherently quieter, more stable, and gives less trouble with chemical interferences. The residual flicker or 'flame noise' may often be the principal obstacle to improving detection limits. The dropwise nature of the aerosol also causes statistical fluctuation of the signal, similar to the 'shot noise' of photoelectric measurements, in both flame emission and atomic absorption.

The efficiency of transport of sample solution to the premixed flame is usually between 5% and 10%. Other more elaborate devices, such as the ultrasonic type, do somewhat better and are preferred in some applications, but are seldom used in flame photometry.

As each aerosol droplet enters the flame, many processes must occur in  $\sim 1$  ms to convert it into a cloud of excited atoms for measurement in the region just above the primary reaction zone. The measured signal depends on aerosol droplet size distribution and its rate of evaporation, volatilization of the resulting solid particles, cooling by solvent evaporation, chemical reactions among the sample and flame species, and especially any combination and dissociation reactions involving analyte atoms, including ionization and electron recombination. Some of these may be manipulated to advantage by the analyst; flame richness is especially important. Undesirable reactions involving sample constituents also require attention: these sample-dependent chemical interferences, discussed below, have received much study.

In spite of the many processes occurring, flames are relatively stable and analyte atom formation and excitation may be made reproducible to within 1% for a sufficient length of time. In this regard, they are superior to high-voltage sparks and d.c. arcs and compare well with various plasmas and low-pressure gas discharges.

## Flame Spectrometers and Filter Photometers

The simple and inexpensive flame photometers now widely used in clinical laboratories are designed to determine sodium and potassium in blood plasma and urine, with lithium as an added internal standard element. At least two of these instruments may be used to determine calcium in plasma and also lithium when it has been administered at high levels for therapeutic purposes. All these elements give intense spectral lines in such samples, even after 100-fold dilution. Their lines are well separated in wavelength from each other. All other metals are present in much smaller amounts, except magnesium, which is very poorly excited in the cooler air–propane flames employed. Interference filters with transmission peak half-widths of several nanometers, sometimes with colored glass filters added, serve to isolate desired spectral lines without using dispersive optics. Read-out is by panel meter or digital display. Recorder connections are provided on some models. Precision is at least as good as 2% RSD; accuracy has been shown to be adequate for intended purposes.

Simpler forms of these instruments were in common use in Europe by 1940. Some could be used for analysis of plant ash solutions and soil extracts for potassium and calcium. The sodium lines were interfered with by the red–orange CaO molecular emission in such samples. A quite remarkable instrument was developed at this time by the Swedish botanist H. Lundegardh. He employed a premixed air–acetylene flame and a small quartz prism spectrograph having the desired wavelength coverage for most purposes on a 5 in. ( $\sim 12.7$  cm) photographic plate. The spectral line images were measured with a microphotometer in such a way as to achieve an approximate correction for spectral background. Up to 40 elements could be determined. He then automated the entire process!

A few of these instruments were imported and used in the USA. But flame photometry was uncommon there until the introduction of the Beckman total–consumption nebulizer–burner, producing a turbulent oxyacetylene flame. It was used with a high-quality silica prism spectrometer, a photomultiplier detector, and very simple electronic null-balancing circuitry. Flame emission analysis for many elements was thus widely practised until atomic absorption equipment became available.

Following the introduction of the NOA flame in atomic absorption by J B Willis in 1965, certain elements could be determined much more sensitively than before. The use of this flame in emission was soon investigated and found to be quite worthwhile.

**Figure 1** Emission spectrum of the nitrous oxide–acetylene flame, somewhat rich (red zone 3 mm high). Scan rate  $12.5 \text{ nm min}^{-1}$ ,  $25 \mu\text{m}$  slits. The principal molecular emission bands are labeled.

This hotter flame has a more complex and intense spectrum than the air–acetylene flame (**Figure 1**). When made fuel-rich, the NOA flame is more strongly reducing than other flames, enhancing its usefulness. To exploit its advantages in emission, a spectrometer with higher resolving power than that of the absorption instruments is preferred, so that the flame background may be more widely spread out and weakened relative to the atomic lines. Line intensity in a spectrometer varies directly with the slit width whereas continuous background intensity varies with the square of the slit width.

A half-metre grating spectrometer with  $25 \mu\text{m}$  slits typically can give a spectral bandpass or effective resolving power of  $0.04 \text{ nm}$  in the first order. With the NOA flame, quite useful detection limits for many elements may be obtained (**Table 3**). Slits of width  $10 \mu\text{m}$  may be used for further line-to-background discrimination when needed, as for the aluminium  $396.1 \text{ nm}$  measurement. To correct for background emission by scanning across a line profile, a wavelength drive at least as slow as  $0.2 \text{ nm per minute}$  is required.

Several commercial atomic absorption instruments contain monochromators with similar dispersion but are seldom equipped with slits giving less than  $0.1 \text{ nm}$  bandpass. Even then the emission mode is more sensitive than absorption, at least for the alkali metals, using the air–acetylene flame. However, their scan speeds, when provided, are too fast for more general use in emission.

The nebulizer–burner combinations perfected for atomic absorption serve equally well in emission. Gas flow controllers must permit igniting and

R, strong oxide-forming elements; L, nonoxide-forming elements; I, other elements.

extinguishing the NOA flame as an air-acetylene flame. The 5 cm slot burner is perhaps most useful. A silica lens is placed so as to form an image of the flame on the face of the slit, which should be masked so that  $\sim 3$  mm of the flame above the primary reaction zone is accepted, including the red zone of the rich NOA flame.

Commercially available d.c. amplifiers with several sensitivity ranges are satisfactory, as are photomultiplier power supplies with stepwise and continuous voltage settings. Meter readout is desirable, but a recorder is more convenient and is often used for background correction. Limitations on sensitivity generally are imposed by flame phenomena, not by the stability or gain of the electronics. Although all these components are readily available, apparently no manufacturer offers a complete instrument optimized for high-quality flame emission work. The spectrometers and polychromators used with

plasmas could of course be used for flame emission, to advantage in certain instances, although this is seldom done: optimum spectral line choices largely differ for the two methods.

## Further Aspects of Flame Emission Work

### Effect of Stoichiometry in the NOA Flame

For best results, somewhat greater attention to detail is needed in flame emission than in atomic absorption spectrometry. Flame richness greatly influences background intensity and, for many elements, line intensity as well, generally with both increasing together but at different rates. The strong oxide-forming elements, denoted by R in Table 3, are more sensitive in rich flames, by as much as 50-fold for certain rare-earth elements. For these, the red CN

molecular emission needs to be increased to at least 1 cm flame height. For nonoxide formers (L in the table) lean flames are suitable; other elements (I) are best determined with a 3–5 mm red flame.

### Linearity of Response

Flame emission intensity often varies linearly with concentration over several orders of magnitude, with the upper limit set by curvature due to self-absorption. With the 5 cm slot burner, linearity is good below  $1 \text{ mg l}^{-1}$  for most elements and nearly perfect below  $0.1 \text{ mg l}^{-1}$ . For potassium this means four orders of magnitude of linearity and for lithium five. The upper limit may be raised by setting the slot burner cross-wise.

### Background Correction

Discussion of this topic is limited here to the aspects most important in flame work. Another article in this Encyclopedia includes a more general treatment.

The wavelength scan of **Figure 1** was made at high speed and does not show the complex fine structure present. With few exceptions, windows with adequate transmission can be found for any analyte. However, the sample matrix often contributes additional background. The molecular spectra of metal oxides are essentially continuous, even at high resolving power. The commonest offender probably is calcium. The familiar strong red emission of CaO spreads over several hundred nanometres; there is a strong narrow band beneath the barium 553.5 nm line and there are weaker bands in the blue and ultraviolet.

With the rather unsophisticated instruments under discussion, background may be corrected for by scanning or by successive online and offline measurements. In general, scanning is needed when background is intense whereas the other method suffices for weak background.

1. *Scanning.* The spectrum is scanned and recorded across the complete line profile at  $\sim 0.2 \text{ nm}$  per minute for perhaps  $0.4 \text{ nm}$  overall (**Figure 2**). The height of the lithium peak above the small CaO fine structure peak on the right is to be compared with that of the calcium standard scan. The correction is accurate to within 2% even though the Ca:Li ratio is  $1.6 \times 10^6$ . The method is slower and requires several millilitres of sample solution. (Chemical interferences obviously are minimal in this example.)
2. *Two- or three-wavelength method.* **Figure 3** illustrates the procedure for the most general case, when the flame background and sample background

**Figure 2** Four 0.3 nm scans of the lithium 670.8 nm line; scan speed  $0.2 \text{ nm min}^{-1}$ . (A) NOA flame only; (B)  $2 \mu\text{g l}^{-1}$  lithium standard solution; (C)  $3.2 \text{ g l}^{-1}$  calcium, as purified  $\text{CaCO}_3$  in  $0.1 \text{ mol l}^{-1}$  HCl, with  $2 \mu\text{g l}^{-1}$  lithium added; (D)  $\text{CaCO}_3$  solution only, same concentration as in (C). All are actual recordings, starting and ending with zero light intensity (beam blocked), showing low electrical noise.

both change with wavelength close to the line. The corrected line intensity is obtained by subtracting the average of  $I_{B1}$  and  $I_{B2}$  from  $I_{L+B}$ . If it is known by trial with typical samples that the background is flat, only one offline reading is needed. The readings should be made at wavelengths removed from the line by perhaps five times the spectral bandpass, where the line profile virtually disappears. The operator must always study the background problem whenever an unfamiliar element-sample combination appears. The two-wavelength method is often required, at least, but is easily accomplished.

A reacting or 'wobbling' quartz refractor plate was introduced for automatic background correction. Placed just behind the entrance slit, its vibration caused the line image to sweep across the exit slit,  $\sim 0.1 \mu\text{m}$  overall. Its motion was synchronized with

**Figure 3** Diagram illustrating the three-wavelength background correction method, when both flame and sample background contributions vary near the line. Online reading in the centre; readings offline by 0.2 nm, one on each side of line. Zero intensity is at the low end of the axis. Each trace starts and ends with flame background intensity.

readout so as to subtract intensities on the sides from that of the line peak.

### Interference Effects

Both chemical and physical effects can cause line intensities for samples to differ from those for simple standard solutions at the same concentration. The chemical effects can be more severe and are treated more fully.

**Chemical effects** The classic example is the suppression of calcium by phosphate, first pointed out in 1877. Such effects arise whenever analytes combine with other sample constituents to alter their rates of vaporization compared with those of the standards. The chief methods of overcoming this and other major effects are presented.

1. Prepare calibration graphs by using standard additions. In effect, each sample is used in preparing its own calibration graph. It is very slow and has various pitfalls: it is rarely used in flame emission in the NOA flame.
2. Add a 'releasing agent', a salt of another metal added in large amount to displace the analyte from its state of different, usually lower, volatility. Lanthanum is most often used, at one hundred-fold or higher concentration than the analyte.

3. Go to a hotter flame. The calcium-phosphate effect virtually disappears in the NOA flame.
4. Alter flame richness. Effects for several elements are diminished in leaner flames. It cannot be used for analytes requiring rich flames, such as rare-earth elements.
5. Separate analyte from matrix. This is most helpful when it is also used to concentrate or enrich the analyte, that is, to transfer it to a smaller volume of solution, perhaps along with other analytes at the same time. A great many methods have been described.
6. Add a bulkier, more volatile matrix. Certain high-boiling point acids, and many organic compounds that decompose without melting when heated, have recently been found to suppress several elements in flames even at concentrations as low as a few milligrams per litre. Rare-earth elements show it most strongly, but several common transition elements also suffer, e.g. cobalt and nickel. When large amounts of other salts are present, as in most practical samples, the effect is much reduced or absent.
7. Suppress ionization by adding high concentrations of salts of easily ionized metals, notably the alkali metals. Analytes having low ionization energies may be partially ionized in hotter flames. Manganese, with a fairly typical ionization potential of 7.4 eV, is ~10% ionized in the NOA flame. Alkali metal salts are added at a few hundred times greater concentration than analytes so as to overwhelm sample-to-sample variation. The same amounts are added to standards. Errors due to ionization may easily be reduced to 1 or 2%.

**Physical effects** Several physical properties mentioned under atom formation are associated with the samples themselves and may need to be controlled. Solution temperature, viscosity, surface tension, and vapor pressure all influence nebulization and transport to the flame. Many of the effects are interdependent and not easily isolated for study. For example, enhancement of signals by the addition of flammable organic solvents such as ethanol was commonly practised at one time. This caused changes in aerosol formation, transport, droplet size distribution, evaporation rate, and flame temperature. Although the solvents decreased flame temperature by partially replacing higher energy acetylene fuel, other processes were accelerated. Stability generally suffered somewhat and signals were often slow to reach their final average values. Organic solvents now are most often used incidentally, in the solvent extraction of chelates of the analytes, to enrich them and separate them from interferences.

Physical effects may be controlled in practice by frequent measurement of standards, rinsing nebulizers with solvent after each sample and performing operations at a constant rate. Automatic sample changers can improve results by performing these operations reproducibly. Partial clogging of the nebulizer uptake tube may be the main source of error remaining, as it may not be noticed until the next standard measurement.

## Practical Applications of Flame Photometry

The widely used clinical flame photometers have been described in the section above on flame spectrometers and filter photometers. Analyte concentrations and their inherent line intensities are such that samples may be diluted greatly and various difficulties avoided. The burners are small and round so that self-absorption is slight and calibration curves nearly linear. Use of lithium added at a high concentration as the internal standard helps to correct for some of the uncontrolled variables.

At higher levels of sensitivity and versatility, flame atomic absorption has replaced flame emission spectrometry chiefly for two reasons. It is easier to build absorption instruments that can be operated reliably by untrained workers than is the case for the equivalent flame emission equipment. And the range of elements determinable in many important sample types is greater by atomic absorption. For agricultural workers, the ability to analyze for zinc, copper and magnesium in their samples led to rapid acceptance of the method. In the environmental and health-related sciences, the toxic elements lead, cadmium, selenium, and others suddenly became much easier to determine. The development of electrothermal atomizers, as attachments for the basic absorption instruments, made them still more valuable.

At present, flame emission still retains advantages in approximately the same area in which it began, determination of alkali metals. However, sodium and potassium are so abundant that they are readily determined by absorption in most sample types. Rubidium has been used as a tracer in studies of insect-plant relationships, taking advantage of its low natural abundance, low toxicity, and great sensitivity by flame emission. The higher red-sensitive photomultipliers such as RCA 4840 should be used beyond 600 nm.

Lithium, however, is unique in its suitability for determination by flame emission, especially at very low levels. Even the plasmas are inferior for lithium because of the very high ionization they produce:  $2\text{ }\mu\text{g l}^{-1}$ , the detection limit often quoted for lithium, is poorer by at least 100-fold.

Lithium is a fairly common element: its abundance in the earth's crust is greater than those of copper and zinc. It too may be determined in many samples by flame atomic absorption. However, flame emission in the NOA flame was shown to be valuable for determining lithium in very small animal tissues at normal physiological levels. The  $10\text{ ng l}^{-1}$  detection limit permitted analysis for lithium in individual rat pituitaries at  $\sim 30\text{ }\mu\text{g Li per g dry weight}$ , and eventually enabled establishing the essentiality of lithium in the rat.

Beyond the alkali metals, occasional examples of the use of flame emission have been presented. Ytterbium has been used as a tracer in digestibility studies in large animals. Flame atomic absorption for this element was beset by many interferences when the wet-ashed excreta were analyzed directly. A simple rapid carrier precipitation technique was devised, with lanthanum oxalate as the carrier and the phases separated by centrifuging. A small aliquot of the digests could be taken and all steps performed in a 15 ml centrifuge tube. When combined with flame emission in the NOA flame, the method was sufficiently sensitive, reliable, and rapid. To employ atomic absorption, the method has to be scaled up 10-fold or more.

Table 3 may suggest further applications, especially when analysts need to avoid the high costs of plasma methods. With four exceptions, all elements listed give at least three times lower detection limits by flame emission than by flame atomic absorption. All may be considered sensitive in an absolute sense, with detection limits below  $0.1\text{ mg l}^{-1}$ . The four exceptions are chromium, iron, magnesium, and manganese. These elements are widespread and abundant and their determination by flame emission is generally trouble-free.

The great sensitivities for aluminium, calcium, strontium, and barium by emission should be valuable in geological and agronomic work. Laboratories engaged in rare-earth element work should have good flame emission equipment available. Although it is not widely realized at present, flame emission in its modern form can be quite useful, even, or perhaps especially, in the well-equipped laboratory.

## Inductively Coupled Plasma

**J M Mermet**, Universite Claude Bernard, Villeurbanne, France

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Early in the 1960s, a number of plasmas were described for the purposes of chemical analysis. This led to the availability of commercial systems for elemental analysis during the mid-1970s. Among them, inductively coupled plasma (ICP) has gained general acceptance as an atomization and a radiation source in atomic emission spectrometry (AES). This article will review the properties of such a plasma and the instrumental design required for its use in AES. It should be noted that a plasma may also be used as an ionization source.

### Basic Principle of Signal Generation

In AES, a source has two roles through its available energy: volatilization and atomization of the sample to obtain free atoms, and excitation (and ionization) of the atoms. The subsequent radiative de-excitation of the excited species is used to obtain the specific spectra of the elements present in the sample. A dispersive system is used to isolate the analytical lines (Figure 1). Among the various sources, plasmas were found to be the most suitable because of their properties. A plasma is an ionized gas that is macroscopically neutral. If a gas X is used, a plasma can be described by the following equilibrium:

$$X = \sum_{n=1}^q X^{n+} + \sum_{n=1}^q ne$$

where  $X^{n+}$  is an ion with  $n$  charges and  $e$  is the electron. Some of the properties of ideal gases, such

**Figure 1** Schematic diagram of an ICP system. Key: (A) HF generator; (B) torch; (C) plasma; (D) sample introduction system; (E) injector; (F) collimating system; (G) dispersive system; (H) photon detector; and (I) data acquisition, processing, and editing.

as the relationship between pressure and volume, still apply. However, the presence of charged particles (ions, electrons) leads to plasmas exhibiting different properties from those of ideal gases in terms of viscosity and thermal conductivity.

To create a plasma it is necessary to supply external energy to the electrons in order to ionize the gas. In this, a plasma differs from a flame, which derives its energy internally. An external energy source must be available that represents a significant constraint. However, it is possible, through the external source, to maintain a certain degree of control over the properties of the plasma. In practice, the plasma acts as an energy reservoir.

### Instrument Design

One of the most common ways to sustain a plasma is to use a high-frequency electrical field produced by an electrical generator. Kinetic energy is provided to the species in the plasmas to facilitate ionization of argon. The electrical field is produced through an induction coil, so there are no contaminating electrodes. This type of plasma is therefore called an ICP. Several types of oscillators are used to generate the high-frequency current: the free-running

**Figure 2** Schematic diagram of an ICP torch. Key: (A) plasma (outer gas); (B) auxiliary (intermediate) gas; (C) aerosol carrier gas; (D) emission zone for ionic lines; and (E) emission zone for atomic lines.

oscillator and the crystal-controlled oscillator. The design of a free-running oscillator is based on inductive heating technology, whereas that of the crystal-controlled oscillator is based on broadcasting technology. To be useful, the generator must exhibit enough flexibility to sustain a plasma over a large variation in impedance, corresponding to different working conditions such as ignition and the presence of water and organic solvents. Most generators are currently driven by a computer.

The plasma is created in a special device called a torch (Figure 2), which serves three purposes: it electrically insulates the plasma from the induction coil, stabilizes the plasma, and injects the sample to be analyzed. Because of the skin effect resulting from the high-frequency field, the energy is mostly deposited in the external layer of the plasma. A channel is therefore obtained along the axis of the plasma where the sample can be injected. The sample is consequently confined to the axis of the plasma. The torch materials used must be both insulating and refractory. Current torch designs employ three concentric tubes. The intermediate tube serves to accelerate the gas passing between the outer and the intermediate tubes, which reduces the gas consumption. The inner tube, or injector, serves to introduce the sample into the plasma. The tubes are usually made of silica, with the possibility of using a different material for the injector, such as alumina. Typical outer torch diameters are  $\sim 20$  mm with the inner diameter of the injector in the range 1.5–3 mm. Traditionally, optical observation is performed perpendicularly to the axis of the torch (radial viewing), with the observation height defined with reference to the highest point of the coil. Currently, most

commercially available systems make use of an observation along the axis of the torch, the so-called axial viewing.

Although it might be possible to use any gas to create a plasma, a noble gas is chosen because of its high ionization energy, the absence of stable combination with other elements, and the simple spectrum observed in emission due to the monoatomic nature of the vapor. Argon is usually selected as a compromise between its ionization energy (15.76 eV) and its availability and acceptable cost. ICPs are produced at atmospheric pressure to facilitate sample introduction and to obtain a high kinetic temperature. The kinetic temperature of heavy particles (atoms and ions) is in the range 5000–7000 K. The sample will reach the same temperature if the energy exchange is efficient. In this instance, the atomization processes are complete. The efficiency is related to the residence time of the sample in the plasma. Although laboratory plasmas are slightly ionized (0.1%), the electron number density is of the order of  $10^{20}$ – $10^{21}$  m $^{-3}$  at atmospheric pressure. This value is significantly higher than in a chemical flame. Consequently, interferences due to the presence of easily ionized elements are minimized. However, the spectral background in the ultraviolet (UV) and visible domains, which is due to radiative recombination between the electrons and the argon ions, is high, as its intensity is proportional to the square of the electron number density. It reaches a maximum at  $\sim 450$  nm, which explains the blue color of an argon ICP.

The viscosity of an argon plasma increases with temperature in the temperature range observed with an ICP. It is therefore difficult to introduce a sample carried by a cold gas, as it will encounter a medium whose viscosity is much greater. A major advantage of the ICP is that it facilitates the injection of a sample along its axis, where there is a zone of lower viscosity.

The significant operating parameters of an ICP are the following: generator power (600–2000 W) serving essentially to provide energy for sample dissociation; plasma gas flow rate (8–15 l min $^{-1}$ ) serving to obtain a stable plasma; aerosol carrier gas flow rate (0.5–1.0 l min $^{-1}$ ); and observation height with radial viewing (2–20 mm), which determines a zone within the plasma where the best excitation conditions for atomic and ionic lines are obtained. On most ICP systems, these parameters are computer controlled. They can be optimized and stored in an analytical method. Another parameter is generator frequency (27.12 or 40.68 MHz), which has an influence on plasma configuration and on the required power, as well as on the analytical properties. International regulations are available for high-frequency applications. They imply that both the

excursion range and the intensity of the field should have limited values. However, commercially available ICP systems are sufficiently shielded so that the influence of the high-frequency field on other equipment is negligible.

Although a noble gas plasma would appear to provide a simple medium, many species exist and are competing with one another. Many mechanisms of excitation and ionization have been described to explain the observed spectra in terms of the roles played by electrons and argon ions. The use of argon makes it possible to ionize a large number of the elements of the periodic table. The exceptions are helium, neon, and fluorine. However, it may be difficult to supply enough energy to excite certain ions to higher energy levels, which precludes the observation of such ions. The alkali metals are examples of elements whose ions have too high excitation energies. Most elements will exhibit both atomic and ionic lines, in which case the ionic lines usually provide the best sensitivities. For some elements (e.g., antimony, arsenic, boron, gallium, and phosphorus), only the atomic lines are used for analytical purposes. Moreover, for some elements such as chlorine, bromine, nitrogen, and oxygen, the most sensitive atomic lines are located in the UV at wavelengths shorter than 150 nm. This requires a vacuum (or nitrogen purge) between the plasma and the optical detector, and optical components made of  $\text{MgF}_2$ . Systems that allow a wavelength range down to 120 nm are now commercially available. In practice,  $\sim 70$  elements of the periodic table can be determined using an ICP in AES.

## Sample Introduction Techniques

Although an ICP exhibits a high kinetic temperature, the residence time during which the sample remains in the plasma is limited to a few milliseconds. Consequently, it is necessary to introduce the sample in the form of small liquid or solid particles of the order of a few micrometers to ensure complete volatilization and atomization. This is a serious constraint in the design of the sample introduction system.

In general, solids are introduced in the form of fine particles, either in suspension in a liquid (slurries) or in a gas stream. Spark ablation and laser ablation can also be used for this purpose. Direct introduction of solids, placed in a refractory vessel at the base of the plasma, has also been described.

The most common way for a sample to be introduced into an ICP is a solution. In order to produce fine droplets from a liquid, a nebulizing system is required. To date, the most widely used type is the pneumatic nebulizer, which has three

variants: the concentric, the cross-flow, and the V-type. V-nebulizers are less subject to blocking. In using a nebulizer, the aim is to achieve efficient nebulization at a low carrier gas flow rate ( $< 1 \text{ l min}^{-1}$ ). However, the nebulizers in service today provide droplet distributions centered on  $\sim 20 \mu\text{m}$ . It is therefore necessary to add a chamber, called a spray chamber, in order to filter out droplets larger than a few micrometers in diameter. The overall efficiency of the nebulizer associated with the spray chamber is very low – only  $\sim 2\text{--}5\%$  for liquid consumption in the range  $1\text{--}2 \text{ ml min}^{-1}$ . Currently, micronebulizers, i.e., micronebulizers efficient below  $0.2 \text{ ml min}^{-1}$  are commercially available, with efficiency higher than 50%. A pneumatic nebulizer is usually fed via a peristaltic pump to ensure a constant uptake rate irrespective of the viscosity of the liquid.

Ultrasonic nebulizers are free of these difficulties as aerosol production is independent of gas flow, and droplet size is related to ultrasonic frequency. Droplets with diameters of  $\sim 1 \mu\text{m}$  can be obtained with frequencies above 1 MHz. The efficiency is high enough to require the addition of a desolvation system to eliminate water. The desolvation system consists of an oven associated with a cooling system to trap the water vapor. Detection limits are usually improved by a factor of 10 in comparison to a pneumatic nebulizer. Although ultrasonic nebulizers are attractive in this respect, their use is as yet not widespread, due to their prohibitive cost.

Gases can be directly introduced into the plasma. The only limitation is the change in resistivity of the plasma, which can degrade the coupling efficiency between the generator and the plasma. The tolerance of the plasma to the amount of foreign gases is typically below  $0.1 \text{ l min}^{-1}$ . An application of gas introduction is the use of volatile hydrides (As, Bi, Se, Pb, etc.) or the addition of molecular gases ( $\text{N}_2$ ,  $\text{H}_2$ ) to improve the thermal conductivity of the plasma.

In order to avoid solid dissolution, which may be tedious and time consuming, direct solid analysis may be performed by using ablation, i.e., removal of material from a target. Spark ablation may be used for a conductive material, while laser ablation may be used for any type of material. In the case of solids in the form of fine powders, suspensions in water (slurries) may be an alternative to sample dissolution.

A current trend is the coupling of another technique with AES, such as liquid chromatography, ion chromatography, or flow injection analysis, to enhance the capability of the plasma, particularly in the field of speciation (the so-called ‘hyphenated’ techniques). This coupling can be considered as a highly sophisticated sample introduction system. In

general, the interface between the two hyphenated techniques makes use of the standard nebulizing system, although some adaptation may be required.

## Dispersive Systems

The task of a dispersive system is to measure the net line intensity of an analytical line. This includes the measurement of both the gross line intensity and the background. Off-peak background measurements are usually carried out with an interpolation of the background values at the analytical line wavelength. In AES, work is performed essentially in the range 165–800 nm, with Al II 167 nm and K I 770 nm being the lowest and highest wavelengths, respectively. As noted previously, there is a trend to work down to 120 nm for lines such as Cl I 134 nm. Dispersive systems with diffraction gratings are used. Two categories of dispersive systems are used: simultaneous polychromators and sequential monochromators, depending (1) on the type of grating, i.e., plane or concave grating with high line number or plane echelle grating with low groove number, and (2) on the type of detector, either photomultiplier tube or multichannel detector. Polychromators allow several wavelengths to be measured simultaneously. Conventional polychromators make use of a concave grating, and are generally of the Paschen–Runge type, with the entrance slit and the exit slits located on a so-called Rowland circle. A photomultiplier tube is set up behind each exit slit. The wavelength selection is in principle difficult to change. Background correction can be carried out through a small discrete lateral displacement of the entrance slit. Alternatively, multichannel detection can be used for polychromators. With a concave grating, a polychromator is obtained with a linear association of array detectors along the so-called Rowland circle. With an echelle grating, cross-dispersion based on the use of a prism is designed to avoid order overlaps due to the use of a low ruling density but high orders. Consequently, a two-dimensional spectrum is obtained, which is highly suitable for a two-dimensional multichannel detector. The main advantage of a simultaneous system is the speed of measurement. Monochromators work sequentially, by displacing one of the optical components in the dispersive system. They make use either of a plane grating (with an Ebert–Fastié or a Czerny–Turner mount) or a concave one (with a Paschen–Runge mount). In the first instance, wavelength selection is obtained by rotating the grating and in the second instance by displacing the exit slit and detector. An echelle grating monochromator is based on the motion of either of two optical components, grating and prism,

or the exit slit and the detector. Drastic improvements have been made in the accuracy and speed of positioning for wavelength. The positioning is controlled directly by a computer with periodic wavelength recalibration. Two measurement modes can be used: peak search mode and direct peaking mode. The former mode is usually for systems making use of grating rotation, whereas the latter is for systems based on slit and detector displacement. The peak search mode uses a scan over the line profile. The peak intensity is computed with the use of curve fitting. The main advantage of the peak search mode is the knowledge of the shape of the line profile, which can be displayed or printed. However, this mode is time consuming. The main advantage of the direct peaking mode is the speed of measurement but no information is obtained on line profile. When using multichannel detection, this problem is no longer a cause for concern, because in a single shot both the line profile and the adjacent background are measured.

The use of gratings with a large number of lines per millimeter (up to 4200) and that can work in the second order implies that the practical resolution in monochromators is limited essentially by the band pass and the optical aberrations. Practical resolution is in the range 5–20 pm with the highest resolution in the UV range. Similar resolutions are obtained with the use of echelle gratings.

## Spectral and Matrix Effects

Interference phenomena can be classified in two categories: interference that modifies the signal because of a change in the aerosol transport and filtration and a change in atomization, excitation, or ionization conditions due to the matrix or other elements, and interference that disturbs observation of the signal by partially or totally overlapping the analytical line. While the consequences of matrix or interelement effects have been widely described, their origins are still unexplained. The effects usually correspond to a change in the analyte line intensities and a shift in the spatial distribution along the axis of the plasma. However, these effects can be minimized by increasing the generator power and the residence time of the sample, which is obtained by decreasing the carrier gas flow rate and increasing the inner diameter of the injector.

Spectral interferences are much more critical and can result from the spectra of argon, OH, bands and elements injected into the plasma. Argon emits lines only above 300 nm or in the far-UV. Therefore, no unknown lines can be assigned to argon in the range 165–300 nm. Although water is almost entirely

dissociated, the OH species exists below a temperature of 3000 K and its emission is significant  $\sim 300$  nm, which hampers the measurement of a few analytical lines. In the case of elements, spectral interferences occur because of the complexity of their spectra, and the broadening of the spectral lines. This complexity can be explained by excitation phenomena within the plasma, as well as by improvements in the detection systems. None of the wavelength tables that are currently available cover all the lines emitted by an element. Line-broadening is mainly due to the Doppler effect resulting from the high kinetic temperature. Typical full-widths at half-maximum are in the range 1–6 pm. A few elements exhibit hyperfine structure. Elements such as cobalt, iron, molybdenum, niobium, tantalum, tungsten, and uranium are the most interfering. This is why software written for sequential dispersive systems and multichannel detector based dispersive systems allows the selection of an analytical line free of spectral interferences by displaying the spectra of the analyte and the other elements. For each new matrix, it may be necessary to make such a line search.

## Analytical Performance

The AES limits of detection in a solution obtained with an ICP fall between 0.01 and  $50 \mu\text{g l}^{-1}$ . For a very sensitive element such as Be, the best limits of detection are below  $0.05 \mu\text{g l}^{-1}$ , while for a difficult element such as Pb, they are below  $4 \mu\text{g l}^{-1}$  (Table 1). The principal limitation is the high background, which produces significant background noise. As a salt concentration of up to  $50 \text{ g l}^{-1}$  can be used, corresponding limits of detection less than  $1 \text{ mg per kg}$  can be obtained in a solid before dissolution.

ICP-AES is not an absolute method for concentration measurement. A calibration using known standards must be first carried out for each element, and then the concentration of an element in an

unknown solution is determined via the calibration graph. One important feature of the ICP is the large linear response range of over four to six orders of magnitude. Curvatures can be observed at high concentrations because of the self-absorption phenomenon. However, calibration graphs are generally used within a limited concentration range.

The accuracy of an analytical method, i.e., the agreement between the average of the results and a 'true' value, can be estimated by using reference materials. In spite of the large range of materials currently available, it may be difficult to obtain adequate standards for work at trace levels. Use of an internal standard can improve accuracy. An accuracy of 1% can be expected.

The precision refers to two concepts: repeatability, or the dispersion of the results obtained during an experiment where it is assumed that the operating parameters have not changed; and reproducibility, or the dispersion of the results among several experiments. Precision is usually estimated by using either the standard deviation or the relative standard deviation (RSD) of the fluctuations observed for several replicates of the measurements. Typically, the RSD values fall between 0.4% and 2% without an internal standard and can reach 0.1% with the use of an internal standard. The main limitations in the precision results from shot noise and flicker noise. The former noise is related to the random nature of the photoelectrons emitted at the detector level. Its RSD is inversely proportional to the square root of the signal. Flicker noise is mostly related to the sample introduction system, i.e., sample formation and transport. Its RSD is independent of the signal over a large range of concentration.

Long-term stability is an important factor: absence of drift allows the ICP user to avoid periodic, time-consuming recalibration. The main causes of drift are due to changes in the generator power and the sample introduction system efficiency. The latter is usually caused by a partial blocking of the nebulizer or a variation in the spray chamber temperature. Currently, an RSD of 1% can be expected over a period of 4 h. As mentioned previously for precision, use of an adequate internal standard can improve the long-term stability.

## Limitations

One limitation of the ICP is that it is based primarily on the use of solutions. The number of elements soluble in the same solution is limited. Sample preparation is time consuming and there is a risk of loss or contamination at the trace amount level.

**Table 1** Typical limits of detection ( $\mu\text{g l}^{-1}$ ) obtained with an axial viewing-based ICP-AES system

Ag	0.6	Fe	0.2	Sb	1.5
Al	0.2	Hg	1.3	Sc	0.1
As	1.2	I	10	Se	1.5
Au	0.6	K	1.5	Si	1.5
B	0.3	Li	0.5	B	1.3
Ba	0.04	Mg	0.03	Sr	0.03
Be	0.04	Mn	0.05	Ti	0.15
Bi	2.6	Mo	0.2	Tl	1
Ca	0.03	Na	0.6	V	0.2
Cd	0.1	Ni	0.3	W	2
Co	0.2	P	1.5	Y	0.2
Cr	0.15	Pb	1.5	Zn	0.1
Cu	0.18	S	3	Zr	0.3

Obviously, this is not a limitation for samples already in the form of a solution. The use of a pneumatic nebulizer is another limitation of the technique. Besides risk of blocking, most of the instabilities arise from the nebulizer. Nevertheless, the main limitation of ICP-AES is the possibility of spectral interferences as mentioned above. Although the most sensitive lines can be used most of the time, it may be necessary to verify that they are free from spectral interferences when a new matrix is used.

## Applications

Virtually any type of inorganic and organic sample can be analyzed in ICP-AES using the multielement capability of the technique: biological samples, metals, alloys, electronic materials, glass, ceramics, environmental samples, oils, geological samples, and so on. This versatility combined with adequate analytical performance at a reasonable cost justify the current acceptance of this technique, which is illustrated by the number of instrument companies involved in this field.

## Microwave-Induced Plasma

**G M Greenway**, University of Hull, Hull, UK

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Microwave-induced plasmas (MIPs) can be used as excitation sources for atomic emission spectrometry (AES). The main advantage of the MIP over the more commonly used inductively coupled plasma (ICP) is that it can be operated with helium as the support gas, although argon has also been widely used. With helium plasmas halogens and other nonmetals with high excitation energies can be determined with much greater efficiency due to the presence of highly energetic species in the plasma. The microwave plasma is also less expensive to operate than an ICP as it typically runs at lower power and needs less cooling, so that there is lower gas consumption. These factors mean, however, that the plasma is physically small and does not afford a high enough plasma energy density to vaporize or evaporate solid or liquid samples. In practice, this means that the plasma is easily quenched.

## Basic Principles of Signal Generation

To produce the type of MIP used most commonly, a microwave generator operating at 2450 MHz is

connected by a waveguide to a resonant cavity. When switched on, a standing wave is set up in the cavity and at the center of the cavity where the electrical field is greatest there is a discharge tube through which the plasma gas flows. The plasma is initiated by seeding the plasma gas with electrons, usually derived from a Tesla coil. These electrons oscillate with the microwave field, initially being in phase with the applied field, but as the field is reversed the electrons are not able to change direction rapidly enough, and hence a phase lag is initiated between electron motion and field. The accelerating electrons collide with gaseous atoms, causing frequent direction changes. The process continues with the electrons gaining energy from the field and losing energy through collisions until they gain enough energy to excite or ionize an atom. Stabilization of the MIP occurs through repetition of this process and successive collisions between electrons released by ionization and neutral gas atoms until equilibrium is obtained.

The MIP formed is not in local thermodynamic equilibrium, that is, it cannot be characterized by one temperature, but needs defining in terms of the translational, rotational, vibrational, and electron temperatures as well as the more commonly understood surface temperature. The electron temperature is

highest as the energy is first transferred to the chemical species via electron collisions. The surface temperature as measured by a thermocouple or pyrometer has been found to be between 500 and 1000 K for a low-power helium plasma. The excitation mechanism is complex and involves both high- and low-energy electrons, ions, and metastable atoms and molecules. It is thought to be the highly energetic metastable helium species that give the helium MIP its high excitation capacity.

## Instrument Design

The components required to produce a low-power atmospheric helium plasma include a generator, a resonant cavity, and a discharge torch. In the past, the microwave generator was usually from a medical diathermy unit that supplied 100–200 W at 2450 MHz. More recently magnetron tubes manufactured for microwave ovens have been used. These are capable of supplying higher power levels (500 W), giving greater stability to the plasma, which facilitates sample introduction.

The microwave cavity must be designed to transfer power efficiently from the generator to the plasma gas. Usually, a coupling device is used to match the impedance of the cavity and plasma to that of the rest of the system, thus keeping reflected power to a minimum. To account for changes caused by igniting the plasma and different plasma conditions the cavity is often provided with tuning and impedance-matching devices. Performance of the cavity depends both on the material from which it is constructed and the mode in which it operates.

Fields and currents produced in microwave cavities decrease exponentially with penetration into the conductive material. The degree of penetration is called the skin depth and the cavity should therefore be constructed with a material of low skin depth, which is of high conductivity. However, as it is only the surface of the cavity that is important, cavities are usually made from a brass or aluminum substrate with a coating of high-conductivity metal such as silver or copper.

The cavities most often used in earlier work were either the shortened 3/4-wave or 1/4-wave coaxial types, but these were unable to sustain an atmospheric helium plasma. Fehsenfeld introduced a shortened 1/4-wave radial cavity that was improved by Beenakker and with certain minor modifications this proved to be a successful design for sustaining an atmospheric helium plasma due to its strong electrical field. The cavity, shown in **Figure 1**, was designed to have its resonant frequency at 2450 MHz, with a minimal cavity volume so that a high-energy density

**Figure 1** A  $TM_{010}$  type resonant cavity. The position of the coupling loop and the viewing and cooling ports are shown. The discharge tube is centered in the holes at the top and bottom faces of the cavity. (Matousek JP, Orr BJ, and Selby M (1984) Microwave-induced plasmas: Implementation and application. *Reviews in Analytical Atomic Spectroscopy* 7: 275–314.)

at a given input power was attained. The discharge tube was located at the position where the electrical field was a maximum. It was operated in the  $TM_{010}$  mode, where T and M stand for transverse and magnetic, respectively. The subscripts refer to the number of full wavelength patterns around the circumference, the number of half-wavelength patterns across the radius, and the number of half-wavelength patterns across the axis. The resultant cavity had an axially directed electrical field with a maximum at the center. The power was transferred to the cavity by a coupling loop that was mounted perpendicular to the circularly directed magnetic field. The tuning and coupling of the cavity were not ideal and several workers made modifications to improve this design. The designers of the commercially available atomic emission detector (AED) required a cavity that did not need constant retuning and they chose to use a re-entrant cavity with a special coupling loop design.

With conventional MIP discharge tubes the helium plasma forms a bolus in contact with the torch

walls and with no central channel. One of the main practical consequences of this is the short lifetime of the discharge tubes. One approach to improve torch lifetime has been to water-cool the discharge tube by modifying the cavity slightly. This has been found to be successful in reducing erosion of the torch walls as well as in reducing background levels and noise in the detection of silicon and oxygen. Reduction in noise and interference for nitrogen and oxygen detection can also be achieved by adding a window at the exit of the discharge tube to prevent back-diffusion of air. A useful addition to the plasma setup is a gas flow system to allow for solvent venting and the addition of make-up and reagent gases, all of which can greatly improve the plasma performance.

Another disadvantage of the conventional MIP discharge tubes is that the sample may pass around the cooler edges of the plasma and therefore not be excited efficiently. Part of the success of the ICP is that it has an elongated doughnut shape with a central channel into which the sample can easily be introduced. Different torch designs have therefore been investigated where toroidal or turbulent flow of the plasma and support gases have been designed to keep the plasma off the torch walls and to introduce the sample into the center of the plasma.

The optical detection systems used in MIPs are the same as those used for other atomic spectrometers and can be either single or multichannel. Fourier transform-based spectrometers have also been used. Conventional optical systems are best designed if the plasma is viewed from the exit of the discharge tube, as is possible with the  $TM_{010}$  type cavity, rather than through the walls of the discharge tube, which become etched. The commercially available AED uses a computer-controlled silicon photodiode array detector which has multielement detection capability over segments of spectra. In recent years, MIP sources have also been investigated as ion sources for mass spectrometry.

### Alternative Microwave Discharges

The focus of alternative microwave designs has been to produce a plasma that could cope more easily with the introduction of liquid aerosols. Often, higher powers (up to kilowatts) are used to give increased power density and plasma size. One of the original alternative designs was the capacitively coupled plasma, which is generated by transmitting microwaves through a rectangular waveguide to an electrode. This operates at high power and is therefore more robust and can easily cope with liquid sample introduction but tends to be less precise and have a higher background than the MIP.

The surfatron or surface wave device has also been investigated, especially for liquid sample introduction. Instead of using a resonant cavity to sustain this type of plasma, a length of coaxial transmission line with a capacitive gap at one end and a short circuit at the other is used to launch surface waves along the length of the device. The plasma is sustained in a silica tube that is held in a cavity that shapes the axial electric field. Depending on the power, flow rates, and discharge tube geometry, a helium plasma can be formed that consists of an annulus of plasma surrounding a darker central hole. This central plasma channel appears to allow greater sample penetration into the plasma and the plasma is also stable over a wide working range, making it particularly suitable for sample introduction of liquids by different nebulization techniques if operated at high power.

A more radically different approach for liquid sample introduction is the microwave plasma torch (MPT) (Figure 2). In a recent design three concentric tubes were used where the outer two brass tubes acted as a coaxial waveguide for the microwaves eliminating the need for a cavity. The inner quartz channel was nonconducting and the helium plasma that was formed (at power levels 70–200 W) was similar to the ICP plasma, having a central channel that was more efficient for sample introduction as described previously. A sheath gas was used to stabilize the MPT and reduce air entrainment.

Different plasma gases have been used especially argon. A microwave-induced nitrogen discharge at atmospheric pressure has been developed with higher thermal energy which could accept aerosol samples and cope with larger sample sizes (3  $\mu$ g). The plasma was run at powers of  $\sim 250$  W and had a tail flame that reached out of the resonant cavity. A nitrogen MIP based on a  $TE_{011}$  (transversal electric) mode cavity (2.45 GHz, 1.5 kW) was compared with an argon ICP for liquid aerosol sample introduction atomic emission detection but was found to have poorer detection limits by one to two orders of magnitude. Recently, MIP-boosted glow discharge AES has also been investigated. A microsecond-pulse glow discharge source was boosted by an MIP to give a tandem glow discharge source for solid sample and surface analysis applications.

Perhaps the most interesting recent developments, however, have been in the area of miniaturization. A miniaturized MIP gas chromatography (GC) detector has been developed using a single 1.5 mm sapphire wafer (Figure 3). The system uses a microstrip to transmit the microwaves, having top and bottom planar conductors sandwiching an insulator through which the microwaves travel. This design allows high

field strengths in the plasma channel but can be operated using the small, low-cost integrated microwave power supplies used in mobile communication devices. A self-igniting helium MIP can be sustained with a power input of 5–30 W and a gas flow of 50–10 000 ml min<sup>-1</sup>.

## Spectral and Matrix Effects

The background emission spectrum due to the plasma is low for both helium and argon and the spectra of both these gases are well characterized so that

**Figure 3** Microstrip plasma source for helium (He-MSP). The square sapphire wafer is 30 mm long and has a height of 1.5 mm. It has a grown-in channel of 0.9 mm in diameter. The microstrip line has a width,  $w$ , of 0.8 mm. (Bilgiç *et al.*, (2000) *Journal of Analytical Atomic Spectrometry* 15: 579–580; reproduced by permission of The Royal Society of Chemistry.)

specific spectral lines may be avoided. If a particularly low background is needed, wavelength modulation may be used. Other spectral interferences are due to impurities from the support gases and the atmosphere such as carbon dioxide, nitrogen gas, and water vapor, or impurities from the sample introduction system and discharge tube. Memory effects are also a problem due to analyte atoms collecting in etched areas of the discharge tubes.

The matrix effect of major concern in the MIP is the effect of sample introduction on the stability of the plasma due to the fact that the plasma is not in local thermodynamic equilibrium. The size of sample that can be introduced can be very limiting, depending of course on the operating conditions used. The MIP has also been found to be affected by the presence of refractory compounds in the sample matrix, which may promote collisional deactivation of metastable species, thus reducing the excitation ability of the MIP. This can sometimes be overcome by increasing the microwave power. This problem is in addition to the more common chemical interferences that can also occur where the analyte forms involatile oxides. In low-pressure plasmas, signal enhancement has been seen in the presence of alkali and alkaline earth chlorides. This is probably due to the formation of volatile chloride salts that enhance atomization, although it may be that they affect the excitation mechanisms in some way. The lack of local thermodynamic equilibrium in the MIP also means that ionization interferences can be significant because changes in the electron density of the plasma will affect its stability and excitation mechanisms. The presence of easily ionized elements tends to lead to strong enhancement effects (although suppression is sometimes seen).

The use of doping gases to overcome matrix effects, especially when the MIP is being used as a gas chromatographic detector, is widespread. The gases act as scavengers and are added to prevent carbon from depositing on the wall of the discharge tube, because if this occurs severely distorted chromatographic peaks may be obtained. Different gases are used for the determination of different groups of elements. For the simultaneous determination of carbon, hydrogen, chlorine, and bromine, oxygen is the chosen gas; but if elements that form refractory compounds are present, hydrogen would be needed.

## Sample Introduction Techniques

Correct sample introduction is the key to the successful use of the MIP, as unless a modified design is used, it can only cope with such small amounts of sample and solvents tend to quench it. Its main application has been as a detector for GC as gases are less likely to affect the stability of the plasmas, but a considerable amount of effort has been spent developing suitable nebulization systems for solutions. The various techniques are discussed below.

### Solution Nebulization

As described earlier, probably the best approach to introducing solutions into the MIP is to use a different plasma design such as the MPT; however, pneumatic nebulizers can be used with argon plasmas if the sample is desolvated first. Ultrasonic nebulizers have also been used, usually followed by desolvation. A low-power argon MIP was investigated with wet aerosol using an integrated TE<sub>101</sub> rectangular cavity with an ultrasonic aerosol plasma cooling system. It was found to perform reasonably well for environmental samples but the detection limits were not low.

### Electrothermal Atomization

This approach is more successful for liquid and solid samples as the electrothermal atomizer will evaporate the solvent, and vaporize and atomize the analyte before it enters the MIP. This means the plasma has to excite only the sample atoms and the problems associated with the low thermal temperature are overcome, only leaving a restriction on sample size. The sample is passed from the atomizer to the MIP in a stream of the plasma support gas, the flow of which can easily be adjusted to match the requirements of the plasma.

Carbon furnaces and cups have been utilized as electrothermal atomizers but these tend to be rather complex and most work has been with metal strips or filaments of platinum, tantalum, or tungsten.

A liquid sample is applied to the filament, which may be placed directly in the support gas stream. In this simplest of configurations great care must be taken with the evaporation of the solvent to ensure that the stability of the plasma is retained. Alternatively, a valve system can be incorporated to vent the solvent whilst the flow of plasma support gas is maintained to the plasma. For all these systems the emission profiles tend to be very sensitive to any changes in conditions and different conditions are needed for different elements.

### Laser Ablation

Laser ablation has been investigated for MIP sample introduction with some success. The advantage of this technique is that, as with electrothermal atomization, a two-step process is used. The laser is used to volatilize and atomize the sample before it is introduced into the plasma for excitation, thus overcoming any problems with low thermal temperatures in the MIP. The sample is transferred from the laser ablation cell to the plasma via a carrier gas that is usually the support gas. The main problem with laser ablation is lack of precision due to the shot-to-shot variation in laser power and its nonlinear effect on the ablation process. To overcome this several different normalization techniques have been investigated.

A major advantage of this technique is that it can be used for solid samples.

### Chemically Generated Vapor and Gas Introduction

The MIP can be used for direct analysis of gas samples either by generating the plasma in the sample, for example, when looking for impurities in argon, or by injecting the gaseous sample into the plasma. Alternatively, an analyte in a liquid sample can be converted to a vapor by chemical reaction and the vapor can then be flushed into the plasma support gas stream via drying tubes. Perhaps the most widely used of these techniques is hydride generation, which can be used for the determination of several elements including arsenic, antimony, and selenium. The other well-established technique used is the cold-vapor mercury method in which mercury compounds are reduced by SnCl<sub>2</sub>. Generators have also been designed to produce volatile chlorides such as bismuth chloride and volatile carbonyl compounds such as nickel carbonyl and halogens.

### Gas Chromatography Detection

The main application of the MIP atomic emission spectrometer has been as a detector for GC, where it is more commonly known as an AED.

A commercially available GC–AED system has been available since 1991, this was originally produced by Hewlett Packard (now Agilent) but in 2002 the product was transferred to a partner company, Joint Analytical Systems GmbH (JAS). Initial attempts at combining GC with MIP were made difficult because only packed separation columns were available and the flow rates and sample sizes for these chromatographic systems were too great for the MIP so that complex venting systems were necessary. The introduction of the capillary column much simplified the GC–MIP interface. The capillary columns used much slower flow rates and smaller samples so that the interface could be achieved by placing the end of the column into the discharge tube only a few millimeters away from the plasma. Loss of sample on transfer was therefore unlikely, although the torch design did need modifying so that the plasma support gas supply was not interrupted. In the new commercial systems a solvent venting system has been retained, as this still tends to give better peak shape and allows the injection of larger sample sizes up to 100  $\mu\text{l}$ .

The advantage of the MIP as a detector for GC is that it is sensitive and can be used in two modes. It can be used as a selective detector for organic compounds containing heteroatoms such as halogens or phosphorus in pesticides. Alternatively, if the system has multielement detection capabilities several elements can be monitored simultaneously and empirical formulae can then be calculated. To a certain extent it is possible to have compound-independent calibrations with an MIP because the plasma breaks down most compounds into their constituent elements. This is particularly useful if calibration standards are not available because it allows the quantification of a whole series of compounds with a specific heteroatom based on a calibration for one analyte with the selected heteroatom. However, there are problems with this technique because the elemental response has been shown to alter in chemically different compounds unless great care is taken. This is probably due to difficulties in the atomization process. In recent years there has been a great reduction in the cost of GC–MS (mass spectrometry) and due to its high sensitivity this technique has tended to take over from the GC–AED. The ability of the GC–AED to selectively detect specific atoms is however still of great use and some workers have used hybrid systems with both MS and AED for identification purposes.

#### Detection for Other Separation Techniques

Because the MIP has been such a successful detector for GC, it was inevitable that workers have tried to

extend its use. For liquid chromatography the problem of introducing a liquid into the plasma has been addressed. One way to overcome this is to use a moving wheel. The column effluent is directed as a mist onto a continuous moving wheel interface. The solvent is then evaporated with a flow of hot nitrogen. This leaves the dry analyte residue that is carried by the wheel into the plasma for volatilization, atomization, and excitation. For supercritical fluid chromatography, a surfatron has been used with carbon dioxide and dinitrogen oxide as the chromatographic carrier gas. The conditions were optimized and evaluated. Limited work has also been published on coupling the MIP with capillary electrophoresis using an ion-exchange interfacing capillary. A plasma has also been created directly onto a thin-layer chromatography plate by connecting the inner conductor of a coaxial cable to a stainless steel capillary tube through which helium plasma gas could flow. Further developments in these areas are likely to continue.

## Applications

Despite the problems described above the MIP has been used for many applications. The limits of detection obtained for the system very much depend on the sample introduction technique and are best either for vapor introduction or preatomization systems. The major application of the MIP has been as a detector for GC, either in the selective mode or for determining empirical formulae with multielement detection systems. Table 1 shows the limits of

**Table 1** Analytical characteristics of AED detection for selected elements

Element	Wavelength (nm)	LOD ( $\text{pg s}^{-1}$ )	Selectivity over carbon ( $\times 10^{-3}$ )

detection, selectivity, and dynamic range obtainable with an AED.

In the selective mode this type of system is particularly useful for speciation studies and has been used to determine different organolead, organotin, and organomercury compounds in environmental samples such as fish, water, and air. **Figure 4** shows chromatograms obtained for the rapid simultaneous determination of methyl mercury, inorganic mercury, and mono-, di-, and tributyltin species in water samples. The analytes were derivatized for analysis and concentrated using headspace solid-phase micro-extraction before injection into the GC. By using a

multicapillary column with the commercial AED system, mercury and tin compounds were detected at low ppt-levels in 5 min timescales. The detector has also been widely used for the determination of both halogen- and phosphorus-containing pesticides in biological samples and for industrial applications where heteroatoms such as sulfur and halogens need to be determined in oils, polymer additives, and pharmaceutical compounds.

## Introduction

Atomic fluorescence spectrometry (AFS) is an analytical method used to determine the concentration of elements in samples. The sample is converted to gaseous atoms, and the element of interest is excited to a higher electronic energy level by a light source. Following excitation, the atoms are deactivated by the emission of a photon. The measured fluorescence is this emission process. Instrumentation for AFS

includes a light source to excite the atoms radiatively; an atom cell to convert the sample into gaseous atoms; and a detection system to collect the fluorescence radiation. The combination of a tunable laser system as the light source and an electrothermal atomizer (ETA), or graphite furnace, as the atom cell provides an instrument that can determine femtogram ( $10^{-15} \text{ g}$ ) quantities of many elements. Commercial AFS instrumentation employs vapor-generation techniques that can provide sensitivity for several elements to the parts per trillion (ppt) level. This article briefly reviews basic principles and instrumentation of AFS, and discusses the technique's analytical figures of merit, including its detection limits and linear dynamic range of calibration curves.

In addition, physical phenomena that hinder AFS analysis, including background signals, are discussed, along with methods to minimize their effects. Representative applications of AFS are described to demonstrate the ability of the technique to determine elements in samples.

## Basic Principles of Atomic Fluorescence

AFS is a method of elemental analysis that involves the use of a light source to excite gaseous atoms radiatively to a higher energy level, followed by a deactivation process that involves emission of a photon. This emission process provides the measured fluorescence signal. AFS can be distinguished from the related atomic spectrometric techniques of atomic absorption spectrometry (AAS) and atomic emission spectrometry (AES) because it involves both radiative excitation and deexcitation.

### AFS Transitions and Spectra

AFS excitation and deexcitation processes involve changes in the energy of valence electrons and are called electronic transitions. Analytical applications of AFS employ transitions in the ultraviolet (UV)–visible region of the electromagnetic spectrum (between 200 and 800 nm). AFS transitions may involve a combination of absorption, fluorescence, and non-radiative processes.

Resonance fluorescence involves radiative excitation of an atom from the ground state 0 to an excited state 1, followed by the emission of a photon (fluorescence) to deactivate the atom (Figure 1A). Resonance fluorescence is frequently the most intense transition for a given element, and is usually

employed when conventional (nonlaser) light sources are employed.

In a nonresonance fluorescence transition, the photons involved in absorption and fluorescence processes have different wavelengths (Figure 1B). The particular transition shown in Figure 1B is called Stokes direct-line fluorescence, which is frequently used for AFS with laser excitation. Nonresonance transitions have the advantage that a wavelength selection device can be used to distinguish between fluorescence and scattered source radiation.

Atomic fluorescence spectra are composed of a number of narrow lines whose width at half-maximum is typically 0.005–0.01 nm. The narrow width of AFS lines compared to molecular fluorescence spectra obtained in solution (whose width is frequently 10–100 nm or more) is due to the absence of vibrational and rotational transitions in atoms and the presence of the atoms in the gas phase.

### AFS Radiance Expressions

The expressions for the fluorescence radiance depend upon the intensity of the light source. For a relatively low-intensity (conventional) light source, the fluorescence radiance ( $B_F$ ) for a resonance transition (Figure 1A) is given by

$$B_F = GYE(\lambda_0)\sigma(\lambda)n_T \quad [1]$$

where  $G$  considers the geometry over which fluorescence is collected;  $Y$  is the fluorescence yield, which describes the fraction of atoms that are not quenched by collisions, and is typically 0–0.5;  $E(\lambda_0)$  is the irradiance of the light source at the central frequency of the absorption transition;  $\sigma(\lambda)$  is the absorption cross-section, which describes the ability of atoms of an element to absorb light; and  $n_T$  is the total number of atoms present in the atom cell.

Several conclusions can be drawn from eqn [1]. First, quenching reduces the fluorescence signal when low-intensity light sources are employed. Second, under these conditions, the fluorescence intensity is directly proportional to source irradiance (Figure 2). Under these conditions, the use of a more intense light source increases the fluorescence signal size. Third, the fluorescence signal is proportional to the number of atoms, indicating that AFS can be used for quantitative analysis.

A different expression for the fluorescence radiance is employed by high-intensity sources (lasers):

$$B_F = GFAn_T \quad [2]$$

**Figure 1** AFS transitions: (A) resonance fluorescence and (B) nonresonance fluorescence. Radiative transitions are shown by solid lines; nonradiative transitions by dashed lines.

where  $F$  is a constant that includes Planck's constant and the central frequency of the absorption

**Figure 2** AFS saturation curve.

transition, and  $A$  is the Einstein coefficient for fluorescence, which describes the rate of emission from the excited state. At high source intensities, the fluorescence signal is independent of the fluorescence signal yield and the source intensity. The saturation curve (Figure 2) shows that the fluorescence intensity increases with source irradiance until a maximum signal is obtained. This condition is called saturation. The high sensitivity of laser-excited AFS (LEAFS) is due to the ability of a laser to achieve saturation and therefore provide the maximum possible fluorescence signal.

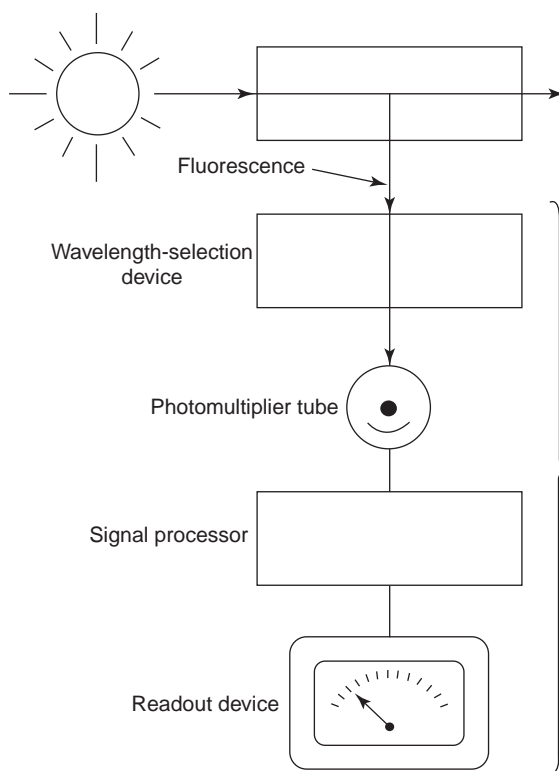

## Instrumentation

AFS was developed as an analytical technique in the 1960s and 1970s following the commercial development of AES and AAS instrumentation. For most elements, AFS detection limits (minimal detectable signal) were about the same as those of AES and AAS, and hence instrument companies did not have a compelling reason to develop AFS instrumentation. Hence, commercial development of AFS instrumentation has been relatively limited.

The principal components of AFS instrumentation are shown in Figure 3. These include a light source, to excite the atoms radiatively; an atom cell, to convert the sample into gaseous atoms; and a detection system, which consists of a wavelength selector, a photodetector, a signal processor, and a readout device. The detection system is usually orientated at  $90^\circ$  or  $180^\circ$  with respect to the light source to minimize the amount of stray source light reaching the photodetector.

### Light Sources

The light source is employed to excite atoms radiatively in the atom cell. From the discussion in the section on AFS radiance expressions, it is clearly advantageous to use an intense light source to obtain

**Figure 3** Instrumentation for AFS.

the maximum AFS signal. Light sources for AFS can be classified into two primary types: conventional (nonlaser) sources and laser sources.

**Conventional light sources** A significant amount of research has been done to develop more intense conventional sources to increase the fluorescence signal size. Conventional light sources that have been used for AFS include hollow cathode lamps (HCLs), electrodeless discharge lamps (EDLs), and continuum sources.

**Hollow cathode lamps** A HCL is composed of a silica envelope that contains 1–5 Torr of argon or neon and two metal electrodes. HCLs are almost ideal line sources for AAS because of their high stability and narrow linewidth (0.002 nm), but their relatively low intensity is a disadvantage for AFS. High-intensity hollow cathode lamps (HI-HCLs) provide increased intensity by use of an additional electrode to separate the atomization and excitation processes. The irradiance of the HI-HCLs is a factor of 20–100 times greater than that of conventional HCLs, and provides better sensitivity for AFS.

**Electrodeless discharge lamps** EDLs employ either microwave energy (microwave-excited EDLs) or radiofrequency energy (radiofrequency-excited EDLs)

to atomize and excite analyte atoms in a sealed silica tube containing an inert gas at low pressure. Microwave-excited EDLs have been commonly employed for AFS because of their high spectral irradiance, which for many elements is a factor of 10 higher than for HI-HCLs. In spite of their high intensity, the use of microwave EDLs is limited due to their commercial unavailability.

**Continuum sources** Continuum sources, unlike the line sources discussed above, offer the potential for multielemental analysis with a single excitation source. High-pressure xenon-arc lamps have been most widely used as continuum sources for AFS because of their high intensity. Each lamp consists of a silica envelope that contains 10–30 atm of xenon and two electrodes to excite the xenon. Improved sensitivity is obtained by the use of a parabolic mirror to focus the emission into an intense beam.

**Lasers** Lasers provide sufficient intensity to saturate atomic transitions, and hence provide the maximum fluorescence signal. For LEAFS, the laser must be capable of generating wavelengths throughout the UV and visible regions in order to excite as many elements as possible. These requirements necessitate the use of a laser system composed of three components: a pump laser, a dye laser, and a frequency doubler.

A pump laser emits light of a single wavelength that is obtained in the form of pulses whose duration ranges from 3 to 200 ns. Commonly used pump lasers include nitrogen, excimer, and neodymium–yttrium aluminum garnet (Nd:YAG) lasers. The Nd:YAG laser requires a frequency doubling system to convert its infrared radiation into visible light to pump a dye laser. Excimer lasers have been commonly used for LEAFS because of their relatively high pulse energies (10–1000 mJ) and their relatively high repetition rates (up to 1000 pulses per second). A high repetition rate is desirable because the AFS detection limit is inversely proportional to the square root of the repetition rate.

A dye laser employs a solution of a dye that absorbs the pump laser radiation and emits fluorescence at wavelengths that are characteristic of that dye. A wavelength-selective device, such as a grating, is incorporated into the laser cavity. The laser radiation is tuned by moving this device. By appropriate choice of the dye, laser radiation at wavelengths between 320 and 900 nm is obtained. Since the mid-1990s, tunable solid-state lasers have been developed as alternative to dye lasers. Optical parametric oscillator lasers have advantages of broad tuning range and ease of operation compared to dye lasers.

A frequency doubler employs a nonlinear crystal to convert the visible output into UV radiation between 190 and 320 nm by a process called second harmonic generation. Generally, only three or four crystals are needed to cover completely this range of wavelengths. The combination of these components provides a light source with sufficient power to saturate AFS transitions throughout the UV–visible region. The principal drawbacks of the laser systems are difficulty of use, high capital and maintenance costs, and poor reliability.

### Atom Cells

The atom cell converts the sample into gaseous atoms. Generally, it is necessary to convert all standards and samples into solution form by the use of acids or other reagents before introduction into the atom cell. Commonly used atom cells for AFS include cold vapor (CV) cells, flames, and ETAs (graphite furnaces).

**Cold vapor cells** Mercury is commonly determined using a CV quartz cell. Chemical reagents, typically tin(II) chloride, are employed to convert mercury dissolved in aqueous solution to gaseous elemental mercury. A flow of argon is employed to transport the mercury to the quartz cell. CV-AFS is a very simple and sensitive technique, with detection limits as low as 0.1 ppt for commercial instrumentation (Table 1). AFS also has the advantage of a long linear range of its calibration curves, typically four to five orders of magnitude.

**Flames** The most commonly used atom cell for AFS is the flame. A flame is formed by burning two gases, one that serves as the oxidant (e.g., air) and the other as the fuel (e.g., acetylene). A capillary is used to suck the sample solution into the flame by the passage of air past one end of the capillary (the Venturi effect). The solution is converted into an aerosol that is introduced into the flame. Flame detection limits are relatively poor because conversion of a solution into

**Table 1** Cold vapor and hydride generation AFS detection limits and linear dynamic range

Element	Technique	Detection limits (ppt)	Linear dynamic range (orders of magnitude)
Hg	Cold vapor	0.1	4–5
As	Hydride generation	10	4–5
Bi	Hydride generation	10	4–5
Sb	Hydride generation	10	4–5
Se	Hydride generation	2	4–5
Te	Hydride generation	10	4–5

an aerosol results in only about 1–10% of the sample actually entering the flame.

Advantages of flames include their low cost and ease of use. Disadvantages of flames for AFS include relatively poor sensitivity, relatively low temperatures, and high chemical reactivity, which may allow the analyte to form molecules and causes a reduction in the fluorescence signal (chemical interferences).

An alternative method of sample introduction for the hydride-forming elements (antimony, bismuth, arsenic, selenium, tellurium, tin) is called hydride generation (HG). Aqueous samples or standards are treated with sodium borohydride and hydrochloric acid to form the volatile hydrides (e.g.,  $\text{SbH}_3$ ), which are transported to an argon–hydrogen diffusion flame. A schematic diagram of a commercial HG system is shown in **Figure 4**. The flame decomposes the hydrides into gaseous atoms. HG provides much lower detection limits than conventional flame techniques because of the higher atomization efficiency and the low spectral background from the relatively cool diffusion flame. Detection limits between 2 and

10 ppt are available using commercially available AFS instrumentation (**Table 1**).

**Electrothermal atomizers (graphite furnaces)** ETAs, also called graphite furnaces, are widely used atom cells for AAS. The atom cell consists of a graphite tube (25–30 mm long by 4–6 mm ID with a 1 mm wall thickness), which is mounted between two electrodes. The temperature of the graphite tube is varied from room temperature up to 2700°C by the application of up to 12 V and several hundred amperes across the furnace by a power supply. A volume of between 5 and 100  $\mu\text{L}$  of sample is introduced into the tube through a sample port. An inert gas such as argon surrounds the tube to prevent decomposition in the presence of oxygen.

Three heating steps are required to obtain a furnace signal. First, the furnace is heated to between 100°C and 200°C to remove the solvent in the drying step. The temperature of the furnace is then raised to 300–1500°C to try to remove as much nonanalyte material in the sample as possible without the loss of

**Figure 4** Sample preparation module of a commercially available AFS instrument. (Reprinted with permission from <http://www.psanalytical.com>.)

**Figure 5** Front-surface illumination for graphite furnace LEAFS.

analyte. This is called the pyrolysis step. The furnace is then heated to a sufficiently high temperature to produce analyte atoms in the atomization step. A transient signal is obtained whose temporal width is typically 3–7 s.

The principal advantage of the ETA compared to a flame is higher sensitivity. ETA-AAS detection limits are one to three orders of magnitude lower than flame AAS detection limits for two reasons. First, the entire sample is introduced into the furnace, without the low efficiency of a flame. Second, the residence time (period of time that atoms remain in the atom cell) of atoms in a furnace is 3–7 s, while atoms remain in a flame for only a few milliseconds.

A considerable body of work has been performed using ETAs with LEAFS. Fluorescence is collected from a graphite tube using a collection scheme called front-surface illumination (Figure 5), which is the collection of fluorescence at  $180^\circ$  to the direction of the laser beam. A mirror, through which a hole is drilled to allow passage of the laser radiation, is used to collect fluorescence along the bore of the tube. Front-surface illumination allows the use of unmodified graphite tube furnaces for LEAFS.

Table 2 compares the detection limits of ETA-LEAFS with those of ETA-AAS. LEAFS detection limits are typically one to five orders of magnitude lower than those of ETA-AAS. In addition, calibration graphs for ETA-LEAFS are linear for four to seven orders of magnitude, which is far superior to the two to three orders of magnitude obtained by ETA-AAS.

## Detection System

### Wavelength-Selection Devices

A wavelength-selection device serves to discriminate against light of all wavelengths except for the

**Table 2** Comparison of ETA-LEAFS and ETA-AAS detection limits

Element	ETA-LEAFS absolute limit of detection (fg)	ETA-AAS absolute limit of detection (fg)
Ag	10	500
Al	100	4 000
Au	10	10 000
Cd	0.5	300
P	8000	5 500 000
Pb	0.2	5 000
Tl	0.1	10 000

fluorescence wavelength of the analyte. Monochromators have been frequently employed as wavelength selectors for AFS because of the ease of wavelength selection. A high-resolution monochromator is not required for line-source excited AFS because resolution is determined by the width of the light source rather than the detection system.

Bandpass filters have also been used extensively in AFS instruments. For example, they are employed in the commercially available CV- and HG-AFS instruments. For graphite furnace LEAFS, careful studies have been made that compare the use of monochromators and filters. Detection limits for lead and thallium were improved by two to three times by the use of very narrow (1 nm) bandpass filters.

### Photodetectors

The photomultiplier tube (PMT) has been widely used as the detector for AFS because of its sensitivity and long linear dynamic range. The operation of the PMT is described elsewhere in this encyclopedia. Commercial AFS instrumentation employs a solar-blind PMT, which is highly sensitive for wavelengths in the UV and vacuum UV wavelengths.

## Sources of Background Emission

A background signal is caused by light originating from sources other than analyte fluorescence reaching the photodetector. Although a wavelength-selection device is used to distinguish against background that is not of the fluorescence wavelength, it cannot remove background at the fluorescence wavelength. Important sources of background for AFS include scattered source radiation, atom cell emission, spectral line, and spectral band interferences.

Under many experimental conditions, the largest source of background for AFS is scattered source radiation. Scatter may be caused by source radiation striking particles in the atom cell, by reflections off the atom cell (e.g., in a furnace), or by components of

the sample matrix. Scatter is minimized by the use of a narrow line source to reduce the amount of unabsorbable radiation, and a nonresonance transition to allow the wavelength-selection device to discriminate against it.

A second source of background signal is atom cell emission, which is light produced by the atom cell. Atom cell emission generally increases with the fluorescence wavelength and with the temperature of the atom cell. Hence, for AFS, the temperature of the atom cell should be as low as possible to minimize atom cell emission, but high enough to atomize the analyte without chemical interferences.

Other sources of background include spectral line (nonanalyte atomic fluorescence) and spectral band (molecular fluorescence) interferences. Spectral line interferences are caused by the presence of another element that can absorb source radiation and emit fluorescence sufficiently close to the analyte wavelength to be collected by the detection system. Spectral band interferences involve the absorption of source light by a molecule whose fluorescence is collected by the detection system. Nonanalyte atomic fluorescence and molecular fluorescence are minimized by the use of a narrow line source and a nonresonance transition. This is in contrast to AES, where spectral interferences are sufficiently severe that a high-resolution monochromator is required.

## Methods of Background Correction

Background correction is widely used in AAS to distinguish between the absorption of light by the analyte and other phenomena that reduce the intensity of the light transmitted through the atom cell, such as molecular absorption and scattering of light by particles. AFS methods of background correction are based upon techniques that were originally developed for AAS. Background correction for AFS involves the measurement of analyte fluorescence plus background, followed by a measurement of background only. The subtraction of these two measurements gives a background-corrected signal. The types of background correction used for AFS have depended upon the type of light source employed. Here, three methods of background correction for AFS are described: two-line background correction, wavelength modulation, and Zeeman background correction.

### Two-Line Background Correction

Two-line background correction, which is employed with conventional line sources, uses a second wavelength that is emitted by the light source (or

alternatively, by a second light source) at which background is measured. Background correction is achieved by subtraction of the measurement made at the second wavelength from the measurement made at the analytical wavelength. In order for the technique to work, the second line may not correspond to a fluorescing line in the sample. It is also assumed that the background is the same at both wavelengths, and hence the wavelengths should be close together. Although two-line background correction works reasonably well for dilute samples, it is generally ineffective for samples that contain high concentrations of scattering materials.

### Wavelength Modulation

Wavelength modulation, which has been employed with continuum source and laser excitation, involves alternatively measuring signal plus background at the analytical wavelength and background 0.001–0.1 nm away from this wavelength. Generally, between 10 and 500 measurements per second are made at and away from the analytical wavelength. The instrumentation used to carry out wavelength modulation depends on the excitation source. Wavelength modulation is relatively effective at discriminating against scatter and atom cell emission because the background measurement is made very close to the analytical wavelength, but it cannot correct for background whose size varies near the analytical wavelength (structured background).

### Zeeman Background Correction

Zeeman background correction, which is widely used in AAS, commonly uses an AC electromagnet placed around a graphite furnace to split atomic energy levels of the analyte. For AFS, when the magnet is off, fluorescence plus background are measured. When the magnet is on, the analyte energy levels are split away from the analytical wavelength, so that absorption (and hence fluorescence) cannot occur, and only background is measured. Subtraction of the two measurements provides a background-corrected signal. Zeeman background correction has been used for AFS with EDLs and lasers as the excitation sources. The primary advantage of Zeeman compared to wavelength modulation or two-line background correction is that the correction is made at the analytical wavelength, and hence Zeeman accurately corrects for structured background.

## Applications

With the availability of commercial AFS instrumentation, hundreds of applications have been reported

since the mid-1990s. One of the most important applications of AFS is chemical speciation, which involves quantitative analysis of each of the chemical forms of an element in a sample. Speciation information is necessary in environmental and toxicological applications, because of differences in toxicity between chemical compounds.

For example, although inorganic mercury compounds are toxic, methylated mercury compounds are of special concern because of their ability to penetrate biological membranes and their efficient accumulation. Moreover, inorganic mercury is converted to methylmercury (MMHg) in aquatic sediments by sulfate-reducing bacteria. Because MMHg is retained in the fatty tissues of animals, it accumulates through the aquatic food chain. Contaminated fish pose a potential route of exposure for humans to MMHg.

AFS is well suited to speciation because of its simple instrumentation and excellent sensitivity. Instrumentation typically consists of either gas chromatography (GC) or high-performance liquid chromatography, to separate the various chemical species, with the AFS instrument serving as the detector. GC has the advantages of higher sensitivity and faster analysis times, but it is limited to volatile and thermally stable compounds.

In addition to mercury, AFS has been employed for the speciation of antimony, arsenic, selenium, and tellurium. Samples analyzed include environmental samples (sediments, water, etc.), food (fish, rice, etc.), and biological fluids (urine, blood, liver, etc.). It is anticipated that the applications of AFS will continue to increase because of the technique's favorable analytical characteristics.

## Inductively Coupled Plasma

**E H Evans**, University of Plymouth, Plymouth, UK

### Introduction

Inductively coupled plasma mass spectrometry (ICP-MS) is a combination of two established techniques, namely the inductively coupled plasma (ICP) and mass spectrometry (MS). The ICP is an extremely suitable ion source for inorganic MS because:

- the high temperature of the ICP ensures almost complete decomposition of the sample into its constituent atoms and
- conditions within the ICP result in highly efficient ionization of most elements in the periodic table and, importantly, these ions are almost exclusively singly charged.

A schematic diagram of an ICP-MS instrument is shown in **Figure 1**. The ICP component is very similar to the ICP used for atomic emission spectrometry

and, in the recent past, sample introduction systems, radiofrequency (RF) generators, and tuning networks were often the same for ICP-MS and ICP-atomic emission spectrometry systems, though more specialization has recently been introduced.

### Instrumentation

#### The Inductively Coupled Plasma

The ICP is generated by coupling the energy from a RF generator into a suitable gas via a magnetic field that is induced through a two or three turn, water-cooled copper coil. The RF energy is normally supplied at a frequency of 27.12 MHz, delivering forward power at between 500 and 2000 W. Two gas flows, usually argon, flow in a tangential manner through the outer tubes of a concentric, three-tube quartz torch that is placed axially in the copper coil. The outer and intermediate gases flow tangentially (i.e., they swirl around as they pass through the torch), so the plasma is continually revolving and has a 'weak spot' at the center of its base, through which the inner gas flow, containing the sample, can be introduced. A spark is used to seed the gas with electrons, which then accelerate in the magnetic field and reach energies sufficient to ionize gaseous atoms in the

**Figure 1** Schematic diagram of a commercial inductively coupled plasma mass spectrometer.

field. Subsequent collisions with other gaseous atoms cause further ionization, and so on to form a self-sustaining plasma. This occurs almost instantaneously. The magnetic field causes the ions and electrons to flow in the horizontal plane of the coil, thereby heating neutral argon by collisional energy exchange, and a hot fireball is produced. The hottest part of the ICP has a temperature between 8000 and 10 000 K, which is the temperature of the surface of the Sun, though the analytically useful region is in the tail-flame with a temperature between 5000 and 6000 K.

In the absence of analyte atoms, water, and sample matrix components, the predominant species in an argon ICP will be Ar, Ar<sup>+</sup>, and e<sup>-</sup>, though other species can be important when considering analyte ionization mechanisms. The RF energy used to sustain the plasma is only coupled into the outer region of the plasma, so these species are primarily formed in this region and are thermally transferred to the center and circulate between the outer and central regions. Additionally, when the sample is introduced through the axial channel, the center will contain a flow of cooler gas containing the analyte and species derived from the sample matrix and water.

### Sample Introduction

The commonest form of sample introduction is by means of an aerosol generated using a pneumatic nebulizer. The most commonly used nebulizer is a glass concentric type; however other types, such as cross-flow, ultrasonic, and v-groove, have also been used successfully. Aerosols generated by nebulization are directed through a spray chamber, which is usually constructed from glass, quartz, or an inert polymer. The spray chamber prevents larger aerosol droplets from reaching the plasma, which would otherwise cause flicker and consequent imprecision, and generally the bulk of droplets are of the order of 2–5 µm in diameter when the aerosol exits the spray chamber. One consequence of this is that the sample transport system is inefficient, of the order of 1–15% efficiency, depending on the type of nebulizer used. On exiting the spray chamber the gas stream containing the aerosol is directed through the injector tube, which forms part of the quartz torch, and thence into the base of the ICP. The injector tube has an internal diameter of 2 mm or so, so the 0.6–1.0 l min<sup>-1</sup> of gas flow exiting it has sufficient velocity to punch a hole through the center of the ICP, thereby forming an annular or doughnut shaped plasma. For ICP-MS, the sample must usually contain less than 0.1% dissolved solids to prevent salt build-up on the sampler and skimmer cones.

Once in the ICP, the aerosol droplets are successively desolvated, decomposed, and ionized by the

high temperature of the plasma. If an electron absorbs sufficient energy, equal to its first ionization energy, it escapes the atomic nucleus and an ion is formed. In the ICP the major mechanism by which ionization occurs is thermal ionization. When a system is in thermal equilibrium, the degree of ionization of an atom is given by the Saha equation:

$$\frac{n_i n_e}{n_a} = 2 \frac{Z_i}{Z_a} \left( \frac{2\pi m k T}{h^2} \right)^{3/2} \exp\left(-\frac{E_i}{kT}\right) \quad [1]$$

where  $n_i$ ,  $n_e$ , and  $n_a$  are the number densities of the ions, free electrons, and atoms, respectively;  $Z_i$  and  $Z_a$  are the ionic and atomic partition functions, respectively;  $m$  is the electron mass;  $k$  is the Boltzmann constant;  $T$  is the temperature;  $h$  is Planck's constant, and  $E_i$  is the first ionization energy. In this case, ionization is effected by ion-atom and atom-atom collisions, where the energy required for ionization is derived from thermal agitation of the particles. The degree of ionization is dependent on the electron number density, the temperature, and the ionization energy of the element in question. Taking the average electron number density for an argon ICP to be  $4 \times 10^{15} \text{ cm}^{-3}$  and the ionization temperature to be 8730 K, the degree of ionization as a function of first ionization energy, predicted by eqn [1], is shown in Figure 2. Most of the elements in the periodic table have first ionization energies of less than 9 eV and are over 80% ionized in the ICP. The remaining third are ionized to a lesser extent depending on their first ionization energy, with the most poorly ionized elements being: He, Ne, F, O, N <1% ionized; Kr, Cl <10%; C, Br, Xe, S <30%; P, I, Hg, As, Au, Pt <80%. Such thermal ionization is probably the dominant mechanism of ionization in the ICP, and predominantly forms singly charged ions, which are ideal for analysis by MS.

**Figure 2** Degree of ionization as a function of first ionization energy calculated using the Saha equation.

## Ion Sampling

In order to perform MS on the ions formed in the plasma they must be extracted into the mass spectrometer, which is required to be at extremely low pressure, so the sampling interface must be in direct contact with the plasma. The problem of extracting ions from an extremely hot plasma at atmospheric pressure into a mass spectrometer at  $\sim 10^{-9}$  atm is overcome by making use of a series of differentially pumped vacuum chambers held at consecutively lower pressures. A schematic diagram of the ICP-MS sampling interface is shown in Figure 3. The ICP is aligned so that the central channel is axial with the tip of a water-cooled, sampling cone, typically made of nickel or copper, which has an orifice of  $\sim 1$  mm in diameter. The pressure behind the sampling cone is reduced, by means of a vacuum pump, to  $\sim 2 \times 10^{-3}$  atm so the plasma gases, together with the analyte ions, expand through the sampling orifice to form a shock-wave structure as shown in Figure 3. This expansion is isentropic (i.e., no change in the total entropy) and adiabatic (i.e., there is no transfer of energy as heat), resulting in a supersonic expansion accompanied by a fall in temperature. This supersonic expansion takes the form of a cone with a shock-wave structure at its base called a Mach disk. The region within the expansion cone is called the 'zone of silence', which is representative of the ion species to be found in the ICP, i.e., the ionization conditions have been 'frozen'.

**Figure 3** Schematic of the ICP-MS interface showing the supersonic expansion formed in the expansion chamber, the barrel shock, and position of the Mach disk.

The skimmer cone is another metal cone, the tip of which has an orifice of  $\sim 0.7$  mm in diameter, which protrudes into the zone of silence, and is axially in line with the sampling orifice as shown in Figure 3. The ions from the zone of silence pass through the orifice in the skimmer cone, into a second intermediate vacuum chamber held at  $< 10^{-7}$  atm, as an ion beam. The ion beam can then be focused by means of a series of ion lenses, which deflect the ions along a narrow path and focus them onto the entrance to the mass analyzer.

## Mass Analysis

Mass analysis is simply a method of separating ions of different mass-to-charge ratio ( $m/z$ ). However, since the ions of interest are almost exclusively singly charged the  $m/z$  is equivalent to mass for most practical purposes. There are three types of mass analyzer used for ICP-MS, quadrupole, time-of-flight (TOF), and magnetic sector.

**Quadrupole ICP-MS** Quadrupoles are typically operated in the mass range from 2 to 260  $m/z$  by scanning through the mass range sequentially. Either the whole mass range or selected masses can be scanned; and the speed of the scan (100 ms to scan from 2 to 260  $m/z$ ) makes it seem almost like simultaneous mass analysis. The quadrupole mass analyzer has the advantage of being cheap, reliable, and compact, with single mass resolution which is sufficient for most applications, and is therefore the most commonly used mass analyzer. However, if an extremely high degree of resolution or true simultaneous mass analysis is required, then other types of mass spectrometer must be used.

**Time-of-flight ICP-MS** In quadrupole and sector field mass analyzers, the ion signal is a continuous beam; however, in TOF-MS the ion beam is pulsed so that the ions are either formed or introduced into the analyzer in 'packets'. These ion packets are introduced into the field-free region of a flight tube 30–100 cm long. The principle behind TOF analysis is that, if all ions are accelerated to the same kinetic energy, each ion will acquire a characteristic velocity dependent on its  $m/z$  ratio. The ion beam reaches its drift energy (2700 eV) in less than 2 cm. The ions are then accelerated down the TOF tube with whatever velocity they have acquired. Because all ions have essentially the same energy at this point, their velocities are inversely proportional to the square roots of their masses. As a result, ions of different mass travel down the flight tube at different speeds, thereby separating spatially along the flight tube with

lighter, faster, ions reaching the detector before the heavier ions.

While simple in theory, the TOF analyzer caused numerous problems when coupled with a plasma source such as an ICP. The spread in ion kinetic energies caused by the ion-sampling process results in the ions entering the field-free region of the flight tube at different angles. Another difficulty with ICP-TOF-MS is that ions have to be introduced in 'packets'. This can be achieved, for example, by using an orthogonal interface with a pulsed repeller plate. Background noise can be reduced by using a combination of quadrupole ion optics and an energy discriminator before the detector.

**Magnetic sector ICP-MS** Magnetic sector mass analyzers rely on the fact that ions are deflected by a magnetic field, with ions of greater mass or charge being deflected to a greater extent. However, ions produced in the ICP will have varying energies, 10–20 eV, depending on their point of formation. Magnetic sector mass analyzers require a high-energy (3–8 kV) ion beam for effective ion transmission and resolution, so the ions must be accelerated in a high-voltage field which will accentuate any differences in ion energy. If a magnetic sector is used on its own (single focusing) the difference in ion energy leads to peak broadening and low resolution. In order to overcome this, a combination of an electric and magnetic sector (double focusing), or a hexapole and magnetic sector, can be used.

Double focusing sector field (SF) instruments use electric and magnetic fields to disperse ions according to their momentum and translational energy. The

electric sector is usually (though not exclusively) placed before the magnetic sector, and acts as an energy focusing device, which transmits a narrow band of ion energies, which are then separated by the magnetic sector. A schematic of a double-focusing SF-ICP-MS instrument is shown in Figure 4.

The problem of variable ion energies can also be solved by placing a hexapole collision cell in front of the magnetic sector, into which a small amount of argon gas is injected. Collisions with the argon gas thermalizes the ion beam, reducing the ion energy spread to <1 V. This means that the simpler, single focusing magnetic sector geometry can be used. The ions are then accelerated to 6 kV before entering the magnetic sector.

The main advantage of magnetic sector analyzers is their vastly superior resolution compared with quadrupole instruments. The resolution of a mass analyzer can be expressed as ( $R = M/\Delta M$ ), where  $R$  is the resolution,  $M$  is the mass of the isotope of interest, and  $\Delta M$  is the peak width of the isotope at 5% peak height. The increased resolution is advantageous because polyatomic ion interferences can be resolved from analyte isotopes of interest. Table 1 shows a number of polyatomic ion interferences and the resolution required to separate them from the elemental isotope of interest. Most quadrupole and TOF mass analyzers operate with an upper resolution of 400, which enables unit mass resolution, while magnetic sector instruments for ICP-MS have been operated up to a resolution of 10 000 enabling peaks of fractions of a mass unit to be resolved.

**Figure 4** Schematic diagram of a double-focusing SF-ICP-MS instrument.

Another advantage associated with focusing instruments is that ions of different mass are spatially separated on exiting the analyzer. This fact has been exploited by a number of manufacturers who have developed 'multidetector' instruments. An array of detectors is placed downstream of the analyzer, allowing up to 10 ions to be detected simultaneously. This has the advantage of reducing imprecision caused by temporal fluctuations in the ion beam, thereby improving the precision of isotope ratio measurements to better than 0.01% RSD.

### Ion Detection and Signal Handling

**Electron multiplier** This is the commonest type of detector, and is used to detect ion currents of less than  $10^{-15}$  A. At higher currents a Faraday cup detector is normally used (see below). When the ion beam exits the mass analyzer it strikes a conversion plate that converts ions into electrons. The ions are drawn toward the plate by a strong voltage applied to the conversion plate. On striking the conversion plate the ions stimulate the ejection of electrons, which are accelerated by the voltage applied to the plate. The electrons are multiplied using either continuous or discrete dynodes. A continuous dynode channel electron multiplier is shown in **Figure 5**. This consists of a curved glass tube of  $\sim 1$  mm in internal diameter with an inner resistive coating and a flared end. The multiplier can be operated in one of two modes. In pulse counting mode – the most

sensitive mode of operation – a high voltage of between  $-2600$  and  $-3500$  V is applied to the multiplier, which attracts ions into the funnel opening. When a positive ion strikes the inner coating the collision results in the ejection of one or more secondary electrons from the surface, which are accelerated down the tube by the potential gradient and collide with the wall, resulting in further electron ejection. Hence, an exponential cascade of electrons rapidly builds up along the length of the tube, eventually reaching saturation toward the end of the tube, resulting in a large electron pulse and a consequent gain of  $10^7$  to  $10^8$  over the original ion collision. The electron pulses are read at the base of the multiplier and are approximately 50–100 mV and 10 ns in duration. Alternatively, the multiplier can be operated in analog mode with a gain of only  $10^3$ – $10^4$  so that the multiplier does not become saturated and the pulses vary greatly in size. In this mode the applied voltage is between  $-500$  and  $-1500$  V and the electron pulses are read at the collector electrode where they are amplified and averaged over a short time interval to allow rapid data acquisition. The greatest sensitivity is achieved with the detector in pulse counting mode, but the detector will become saturated at counting rates above  $10^6$  Hz, which are encountered when the analyte is at a high concentration in the sample. If the detector is switched into analog mode it is less sensitive, but can be used for analyte concentrations that are much higher, typically up to three orders of magnitude higher than for pulse counting. Such dual-mode operation results in an extremely large linear dynamic range of up to nine orders of magnitude. A discrete dynode detector consists of an array of discrete dynode multipliers, usually containing 15–18 dynodes, coated with a metal oxide that has high secondary electron emission properties. The dynodes are placed in one of two configurations, either Venetian blind or box and grid fashion. Secondary electrons emitted by the metal oxide are forced to follow a circular path by a magnetic field, so they strike successive dynodes, thereby multiplying the signal.

**Faraday cup** The Faraday cup detector is used for the detection of much higher ion fluxes than the pulse counting detector. It consists of a collector electrode that is surrounded by a cage. The electrode is positioned at an angle in respect to the ion beam, so that ions exiting the analyzer strike the electrode but secondary emissions are reflected away from the detector entrance. The function of the cage is to prevent detected ions and secondary electrons escaping from the detector. The electrode is connected to the ground via a resistor. The ion current striking the electrode is

**Figure 5** Schematic diagram of an electron multiplier showing: (top) continuous; (bottom) discrete dynodes.

neutralized by electron flow from the ground through the resistor. This causes a potential drop which is amplified to create a signal. Currents as low as  $10^{-15}$  A have been successfully measured in this way.

## Performance

Performance characteristics for quadrupole and magnetic sector instruments are shown in Table 2 and Figure 6. The main advantages that ICP-MS has over other techniques are: low detection limits, in the  $0.1\text{--}100\text{ pg ml}^{-1}$  range for quadrupole instruments (Figure 6), with magnetic sector instruments a factor of  $10\text{--}100$  lower; large linear dynamic

**Table 2** Performance characteristics for ICP-MS

	Quadrupole	Magnetic sector
Detection limit ( $\text{pg ml}^{-1}$ )	0.1–100	0.001–0.1 <sup>a</sup> 0.1–100 <sup>b</sup>
Linear dynamic range	$10^6$ $10^9$ dual mode	$10^6$ $10^{10}$ dual mode
Precision (% RSD)	1–2	1–2

<sup>a</sup>Resolution 400.

<sup>b</sup>Resolution 3500.

range ( $10^6\text{--}10^{10}$ ); and rapid multielement capability. However, ICP-MS also suffers from a number of interferences.

**Figure 6** Typical detection limits for quadrupole ICP-MS. Those achievable with magnetic sector ICP-MS are between 10 and 100 times lower.

## Interferences

ICP-MS suffers from two main types of interference, spectroscopic and nonspectroscopic. Spectroscopic interferences arise when an interfering species has the same nominal  $m/z$  as the analyte of interest. The interfering species can be either an isotope of another element (which are well documented and hence easily accounted for), or a molecular ion formed between elements in the sample matrix, plasma gas, water, and entrained atmospheric gases. The molecular ions are less easy to correct for since they will vary depending on the nature of the sample matrix. Some common molecular ion interferences are shown in **Table 1**. Many of these interferences can be overcome by choosing an alternative, interference-free isotope of the analyte, though a sacrifice in sensitivity may result. If a 'clean' isotope is not available then one solution is to separate the analyte from the matrix before the analysis using chemical extraction and chromatography, or use a magnetic sector instrument that is capable of resolving the interfering species from the analyte. Many of these interferences are thought to be formed in the interface due to a secondary discharge. This discharge can be eliminated by operating the plasma at low power, typically 600 W, and modifying the torch by inserting a grounded shield between it and the coil, or by using a center-tapped RF coil. Under these so-called 'cool plasma' conditions interferences due to  $\text{ArO}^+$ , for example, can be eliminated, though the sensitivity for refractory elements and those with high ionization potentials may be reduced. An alternative method of reducing molecular ions is to use a reaction cell prior to the quadrupole. A gas, such as helium, ammonia, or water vapor, is introduced into the cell where it

either reacts with, collisionally dissociates, or neutralizes the polyatomic species or precursors.

Nonspectroscopic interferences are caused by the sample matrix, and are manifest as an apparent enhancement or suppression in the analyte signal in the presence of a concentrated sample matrix. Such effects are thought to be caused primarily by space charge in the ion beam, whereby positive analyte ions are repelled from the ion beam by the high positive charge of the matrix ions, with low mass ions being relatively more affected than high mass ions. Such interferences are usually compensated for by using an internal standard, or by separating the matrix from the analyte before analysis. ICP-MS has very low detection limits so it is sometimes possible to dilute the sample to such an extent that the interference becomes negligible.

## Applications

Applications of ICP-MS cover a wide range of sample types which often make use of its excellent sensitivity and isotope ratio capabilities, such as the determination of ultra-low levels of impurities in semiconductors, long-lived radionuclides in the environment, and geochronology. ICP-MS is well suited to the determination of the lanthanide series of elements in many geological applications. Sample preparation methods are similar to those generally used for trace metals analysis; however, nitric acid is favored for sample digestion because other mineral acids contain elements which cause spectroscopic interferences.

The capability for rapid multielement analysis makes ICP-MS particularly suited to sample

**Figure 7** Sequential elution of  $\sim 100$  fg of each of the actinides using SF-ICP-MS detection. (Adapted from Truscott J, Jones P, Fairman B, and Evans EH (2001) *Analytica Chimica Acta* 433: 245–253 with permission.)

**Figure 8** Variation in  $^{207}\text{Pb}/^{206}\text{Pb}$  isotope ratio with depth in a salt-marsh core, measured using multicollector SF-ICP-MS. The error bars represent the expanded uncertainty ( $K=2$ ) of the isotope ratio measurements. (Adapted from Gehrels WR, Newnham RM, Kirby JR, *et al.* (2001) High-resolution reconstruction of sea-level change during the past 300 years: Geological Society of America Abstracts with Programs, vol. 33, p. A40.)

introduction methods that give rise to transient signals. This means that electrothermal vaporization, flow injection, and chromatographic methods can be interfaced, and many elements monitored in a single run. An example of this, combined with the extremely low detection limits obtainable with a sector field instrument, is shown in **Figure 7**. The actinide elements have been separated from the sample matrix, and partially separated from each other, using TRU-Spec<sup>TM</sup> resin and the isotopes  $^{232}\text{Th}$ ,  $^{237}\text{Np}$ ,  $^{238}\text{U}$ ,  $^{239}\text{Pu}$ ,  $^{240}\text{Pu}$ ,  $^{241}\text{Am}$ ,  $^{243}\text{Am}$  detected in a single run. Detection limits for the transuranic elements were of the order of 2 fg per g in solution.

A major attraction is the ability to perform isotope ratio measurements, e.g., in many geological applications to determine the age of rocks, biological and geological fractionation of elements, anthropogenic origin, stable isotope tracer studies, and isotope dilution analysis. In this respect, magnetic sector

ICP-MS equipped with simultaneous detection is capable of extremely good isotope ratio precision, of the order of 0.01% RSD, and the technique is supplanting thermal ionization MS as the method of choice in many applications because of its much higher throughput. **Figure 8** shows the variation in the  $^{207}\text{Pb}/^{206}\text{Pb}$  ratio in a salt-marsh core, taken at Chezzetcook, Nova Scotia, measured using multicollector sector-field ICP-MS. The ratio varies between 0.8407 and 0.8536 reflecting the changing influences of the underlying mineralogy and anthropogenic inputs. Note the peak in the early part of the twentieth century due to increased industrialization, and between 1955 and 1975, corresponding to increased automobile usage and leaded gasoline, until it was phased out when the ratio fell again.

## Introduction

The defining attribute of laser microprobe mass spectrometry (LMMS) is the use of a pulsed ultraviolet (UV) laser focused on a  $<5\ \mu\text{m}$  diameter spot for one-step desorption-ionization (DI) of components of a local microvolume in a solid. Subsequent separation of the ions according to their mass-to-charge ratio ( $m/z$ ) is achieved using a time-of-flight (TOF) or Fourier transform (FT) mass analyzer, which provides a low or high mass resolution, respectively. The alternative acronyms used are laser probe microanalysis (LPM or LPMA), laser ablation microprobe mass spectrometry (LAMMS), laser ionization mass analysis (LIMA), and laser microprobe mass analysis (LAMMA). A recent development is 'aerosol TOF-mass spectrometry' (aTOF-MS), dedicated to analysis of suspended single particles in the micrometer-size range.

Material properties often depend on the constituents of inclusions as small as a few micrometers large or surface layers with a thickness of 0.1–100 nm. From the 1970s onward, microanalysis has become a major challenge. Initial methods such as electron probe X-ray microanalysis (EPXMA) or dynamic secondary ion mass spectrometry (SIMS) determine elements at the microscopic scale, but charge build-up and beam-induced sample damage hamper their application to nonconducting organic materials.

The use of photons conceptually overcame these problems, but the development of LMMS had to wait for reliable high-power pulsed UV lasers and sufficiently fast electronics, required for panoramic registration of ions from a single laser shot in TOF-MS. Although TOF-LMMS originally aimed at elemental analysis in dielectric materials, its major

strength soon turned out to be the generation of molecular (adduct) ions for molecular weight (MW) determination, together with structural fragments for characterization of functional groups in organic as well as inorganic analytes.

The successful application of TOF-LMMS to a variety of material science problems has provided evidence of the potential of laser microbeam irradiation, in particular when a high mass resolution is available. Fundamental research on DI processes has led to their successful coupling with FT-MS. The resulting FT-LMMS methodology remains unique in combining a microanalytical detection sensitivity with the ultimate identification power and specificity of a mass resolution value greater than 100 000 and a mass accuracy within 1 ppm. Under favorable conditions, monolayer detection is feasible. Although a laser shot creates craters as deep as 0.1–1  $\mu\text{m}$ , the detected ions come from the upper 10–50 nm surface layer. Unlike static secondary ion mass spectrometry (S-SIMS), LMMS can be used to probe the composition of the upper subsurface in the case of accidental contamination. In addition, its applicability to nonconducting thick samples facilitates material research.

## Fundamentals

Despite the proliferating use of lasers in materials processing, the physics of DI process has not been fully understood yet. Analytical use of the methodology requires chemists to develop practical concepts rationalizing the way that detected ions are formed and reflecting the molecular composition of the sample.

Various models attempt to explain the apparent contradiction between the application of destructive power density conditions to thermolabile compounds and the detection of intact molecular (adduct) ions. Most of the concepts therein share

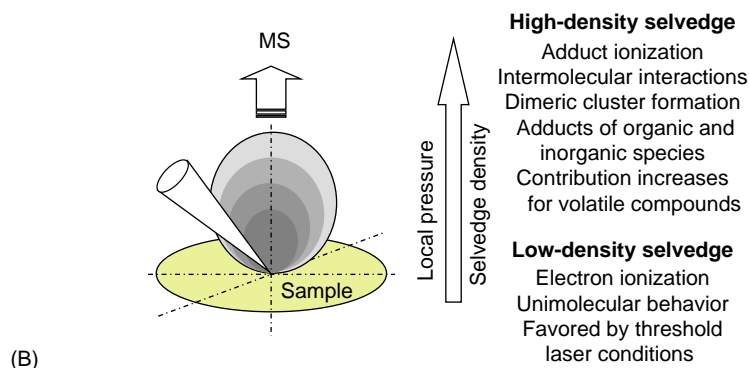

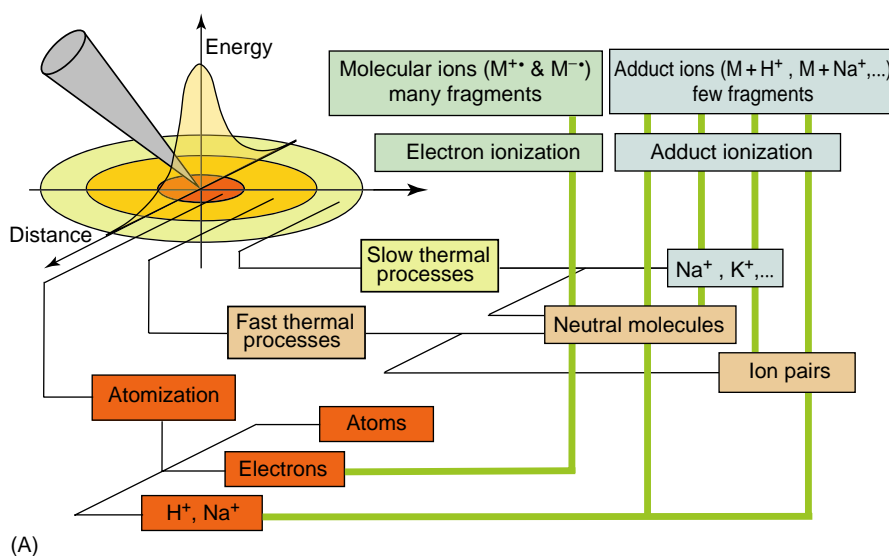

the assumption of a nonthermal process involving mechanisms such as direct ejection of (ionized) species through shock waves, ablation resulting from a nonlinear volume absorption of laser energy by the subsurface, 'solid-state chemical ionization', and photoionization of species already desorbed in the seldge (i.e., dense gas phase above the sample). However, it is often overlooked that thermally driven processes can indeed transfer labile compounds from solids to the gas phase without decomposition. **Figure 1** depicts Arrhenius plots for the vaporization of a thermolabile analyte without and with thermal decomposition. Unless the activation energy of the two routes is identical, the different slopes of the corresponding lines cause their intersection at a given temperature. Hence, there is a temperature range where vaporization prevails over decomposition. Conventionally, a compound is called thermolabile when conductive heating cannot attain this critical temperature before complete degradation of all available analytes occurs. However, laser irradiation of solids leads to a heating rate up to  $10^{10} \text{ K s}^{-1}$ , which brings the sample rapidly into the regime where vaporization prevails over decomposition.

A systematic study of inorganic and organic polyfunctional molecules combined with research on ion formation has allowed us to elaborate a tentative DI model, permitting the formation of detected ions to be rationalized and even predict those of a given analyte structure. The approach illustrated in **Figure 2** basically considers the effects to be expected from the three prime parameters in MS, namely energy, pressure, and time.

**Figure 1** Arrhenius plots describing the temperature dependence of vaporization and thermal decomposition of a thermolabile compound. (Adapted from Daves G (1979) Mass spectrometry of involatile and thermally unstable molecules. *Accounts of Chemical Research* 12: 359–365; American Chemical Society.)

The detection of atomic ions together with molecular (adduct) ions from fragile analytes is linked to the energy gradient created along the surface (**Figure 2A**). A laser impact leads to a combination of processes such as atomization, generation of free electrons, destructive pyrolysis, desorption of intact molecules or ion pairs, and thermionic emission of e.g., alkali ions. Unlike the often-advocated direct ejection of ions, the DI model explicitly considers the initial generation of neutrals, in agreement with the principles of molecular physics. Ionization occurs in the seldge by electron ionization (EI) or adduct ionization (AI). The former process, driven by laser-ejected electrons, generates radical molecular ions with sufficient internal stress to produce numerous fragments. In contrast, ion–molecule interactions between thermal(ized) seldge species form adduct ions. Their fragmentation is restricted to elimination of small molecules. Unlike other approaches that only consider the generation of even-electron parents, the DI model logically explains the detection of radical ions in LMMS. Also the  $[\text{M} - \text{CH}_2]^+$  signals from quaternary methyl ammonium salts are readily linked to the sequence of thermal degradation and AI. The pressure gradient in the seldge is assumed to govern the relative importance of EI and AI (**Figure 2B**). As the density of the neutrals determines the probability of thermalization and ion–molecule interactions, analytes that are readily desorbed with a low laser power density tend to form dimeric and trimeric adducts (e.g.,  $[\text{2M} + \text{Na}]^+$ ), while 'volatile' compounds only show cationization or protonation of single molecules. Finally, the match between the time domains of ionization and mass analysis is considered (**Figure 2C**). This key feature of the DI model makes it applicable to organic and inorganic mass spectra in LMMS, laser desorption with spot diameters of 0.1–1 mm, matrix assisted laser desorption, and S-SIMS. Basically, a given analyte can yield different mass spectra under identical irradiation, depending on the use of a magnetic sector, quadrupole, or FT- or TOF-analyzer. The reason is the bimodal ion production. Specifically, a first ion bunch is generated within 15–25 ns (essentially during the laser pulse), but seldge ionization continues for microseconds. On the other hand, a TOF-analyzer separates only ions if they enter the drift within 10–25 ns. Hence, TOF-LMMS is limited to the first 'prompt' ion contribution, while an FT-analyzer accepts the entire ion production. The existence of a fast and slow ionization process is experimentally supported by kinetic energy ( $E_{\text{kin}}$ ) and emission angle data as well as delayed ion extraction experiments in FT-LMMS performed with external ion sources.

**Figure 2** Rationalization of the detected ions using the DI model in LMMS by the effects of the (A) energy gradient created along the surface, (B) the pressure gradient in the selfedge, and (C) the time domain of ion formation and mass analysis. (Adapted from Van Vaeck L, Struyf H, Van Roy W, and Adams F (1994) Organic and inorganic analysis with laser microprobe mass spectrometry. Part I: instrumentation and methodology. *Mass Spectrometry Reviews* 13: 189–208; Wiley.)

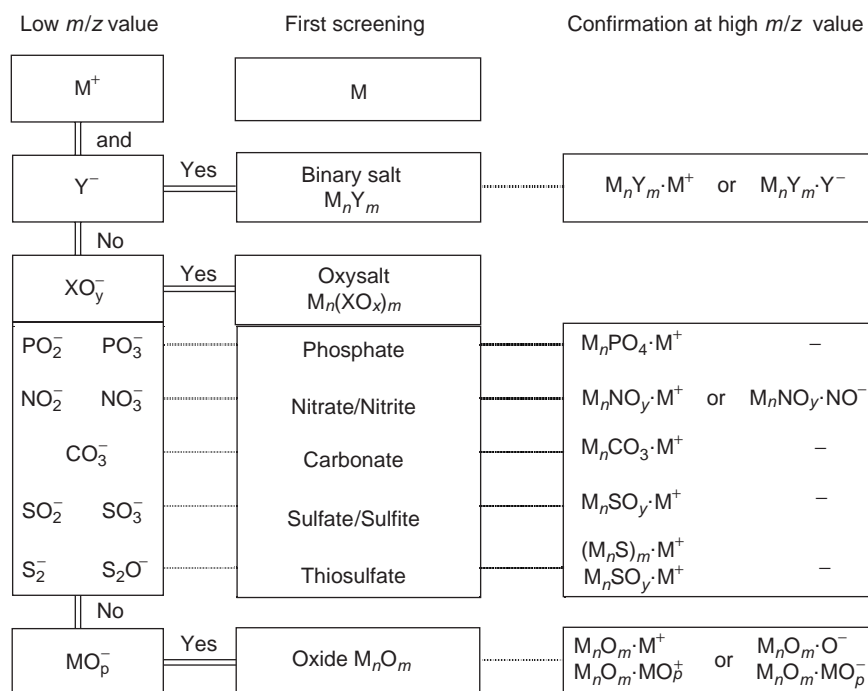

## Diagnostic Use of Mass Spectra

Analytical applications are often based on fingerprinting, i.e., comparison with reference spectra without detailed structural assignment of the ions. This approach fails to exploit the real strength of LMMS, namely the identification of unknown or unexpected compounds. The high mass resolution and accuracy of FT-LMMS are often essential for verifying the elemental composition of detected ions. Deductive identification is a major advantage in e.g., industrial problem solving because many steps, (technical grade) reagents, and various contaminants can be involved. The feasibility of pinpointing one or a few likely causes for the anomaly simply by looking at the mass spectrum readily pays back the cost of an LMMS analysis.

Nowadays, solid-state speciation or molecular identification of inorganic analytes is a hot topic in analytical chemistry. Molecular speciation allows individual components to be identified in mixtures, an impossible task for element or functional group detection methods. In fact, LMMS has been a forerunner in this field. **Figure 3** illustrates the speciation scheme used in FT-LMMS. Basically, the  $m/z$  difference between prominent signals from atomic ions and their adducts, the isotope patterns, and structural fragments such as oxide (adduct) ions in the case of oxysalts readily allow the molecular composition

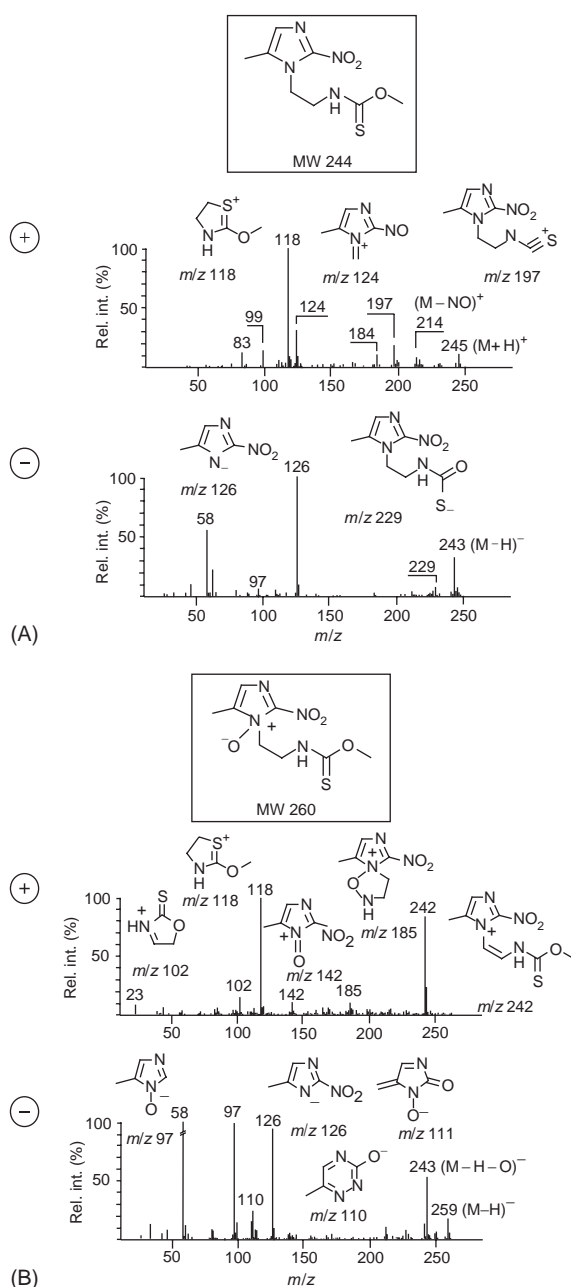

of the analyte to be determined, even at a low mass resolution level. However, FT-LMMS remains of interest for resolving isobars in multicomponent systems, while sampling of the entire ion production increases the relative importance of AI. As a result, the analytical specificity is higher than in TOF-LMMS.

The identification power of LMMS is particularly impressive for organic compounds, not only because of the local scale but also because of the applicability to labile molecules. **Figure 4** shows the mass spectra recorded from the residue of a single peak in analytical high-pressure liquid chromatography. A sample quantity of 1–10 pg is sufficient, while conventional MS often requires material from several elutions to be combined. Even then, positive identification of important metabolites such as N-oxides remains troublesome because classical methods yield identical spectra for the drug and the metabolite. In contrast, LMMS readily distinguishes between both compounds. The structural assignment of the ions follows the well-known mechanisms of gas phase EI and AI. The parent peak in the positive ion mass spectrum of the metabolite refers to the favored loss of  $\text{H}_2\text{O}$  from  $\text{M}^+$ . The detection of odd-electron fragments shows the occurrence of EI, even though the  $\text{M}^+$  ions themselves are not seen here. Furthermore, this example also illustrates how positive and negative ions yield strikingly complementary information on the analyte.

## Instrumentation

### Time-of-Flight Laser Microprobe Mass Spectrometry

Commercially made instruments are available from Leybold-Heraeus (Köln, Germany) and Kratos

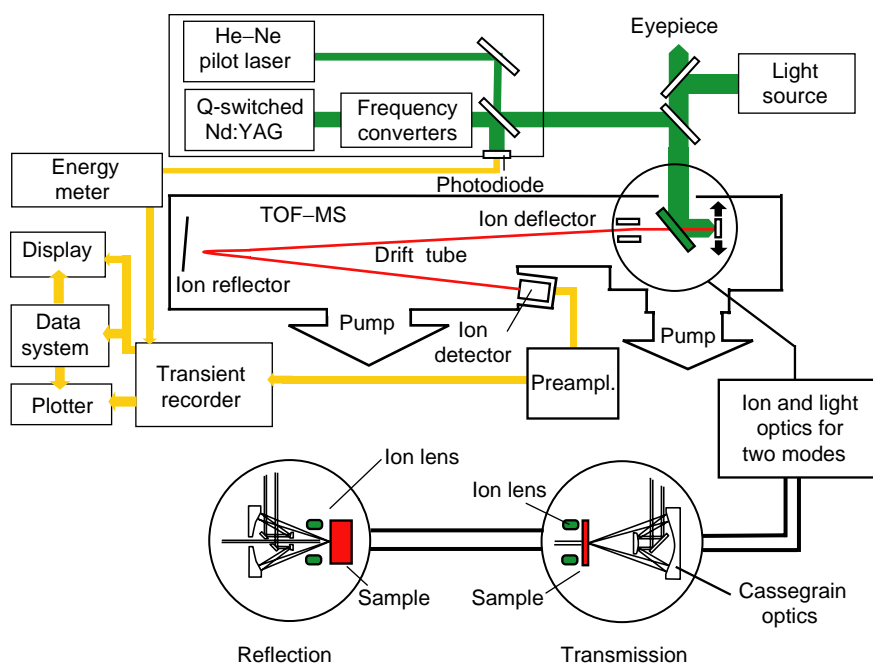

(Manchester, UK) under the names LAMMA<sup>®</sup> and LIMA<sup>®</sup>, respectively. Figure 5 shows a functional diagram of the latter instrument. The ingenious design of interchangeable sample holder and laser optics allows analysis to be performed in reflection or transmission (laser irradiation and ion extraction at the same side or opposite sides of the sample, respectively). The former mode is suitable for surface analysis of samples as thick as 1 cm, while transmission experiments are limited to thin sections (0.25–1  $\mu\text{m}$ ) or micrometer-sized particles on a polymer film. The sample is mounted on micropositioning devices in the high vacuum of the MS. The viewing microscope permits the operator to move the region of interest in the sample under the visible spot of the He–Ne pilot laser, collinearly aligned with the UV beam. Ionization is achieved by a single pulse of 15 ns duration from a frequency-quadrupled Q-switched Nd:YAG laser that delivers up to  $\sim 2$  mJ at  $\lambda = 266$  nm. Absorption filters or polarizers are used to tune the power density on the sample during irradiation between  $10^7$  and  $10^{11} \text{ W cm}^{-2}$ . Although a diffraction-limited spot of 0.5  $\mu\text{m}$  can be achieved in transmission-type instruments, a spot of 1–3  $\mu\text{m}$  is more workable.

The initial assumption that ion formation would be confined to the laser pulse duration has motivated the use of continuous ion extraction. After acceleration to  $\sim 3$  keV, ions travel through the field-free region of 1.5–2 m with a velocity that is inversely proportional to  $\sqrt{m/z}$ . A current electron multiplier, coupled to a 100 MHz memory scope, records the sequential arrival of ions as a function of time. The repulsing field of the ion reflector allows ions with higher  $E_{\text{kin}}$  values to penetrate deeper, follow a longer path, and arrive together with those having lower  $E_{\text{kin}}$  values. The resulting reduction of the peak width improves the mass resolution. The TOF-LMMS design combines simple construction and operation with excellent transmission and panoramic registration for each ion bunch over an, in principle, unlimited  $m/z$  range. However, the mass resolution is lower than expected because nominal mass separation (10% valley criterion) is only feasible up to  $m/z$  values of 500. The reason is the fundamental weakness of coupling laser microbeam DI with TOF-MS due to the specific time domain of ion generation (cf. *supra*, Figure 2C). First, the time spread on the ion bunch limits the mass resolution. Moreover, the slow component of the laser-generated ion population is only detected as an increased baseline.

### Aerosol Time-of-Flight Mass Spectrometry

The successful application of TOF-LMMS to single particle analysis has motivated the development of

**Figure 5** Schematic diagram of LIMA<sup>®</sup> 2A, a commercial TOF-LMMS. (Reprinted from technical documentation, Kratos Analytical.)

dedicated instruments for the individual ionization of suspended particles. Different design options have been tried out and have recently yielded a compact and rugged instrument for field studies. **Figure 6** illustrates the aTOF-MS developed at University of California in Riverside and commercialized later on (TSI, Shoreview, MN). Ambient air is introduced through a nozzle and subsequently mounted skimmers to overcome the pressure difference due to the vacuum in the source. The presence of a particle in a predefined size range is probed through the time difference between the scattering events when it passes through continuous laser beams at a given distance. Once a suitable particle is detected, the Nd:YAG laser ( $\lambda = 266$  nm) fires when the aerosol moves through the waist of the ionizing beam. A brilliant idea that has never been exploited before in LMMS is the use of two TOF analyzers to record the positive and negative ions from the same particle.

#### Fourier Transform Laser Microprobe Mass Spectrometry

Basically an FT-MS is an ion storage analyzer that traps ions in an electrostatic potential valley of  $\sim 2$  eV along the axis of a strong magnetic field  $B$  (4–7 T). The latter forces the ions on circular orbits with a frequency,  $\nu_{\text{ion}}$ , inversely proportional to their  $m/z$  value. Initially, ions orbit with random phase on trajectories with a diameter than 1 mm. A radio-frequency field with frequency  $\nu_{\text{ion}}$  between the

**Figure 6** Schematic diagram of aTOF-LMMS developed at the University of California, Riverside. (Adapted from Gard E, Mayer JE, Morrical BD, *et al.* (1997) Real-time analysis of individual atmospheric aerosol particles: design and performances of a portable aTOF-MS. *Analytical Chemistry* 69: 4083–4091; American Chemical Society.)

transmitter plates allows the ions to take up energy and widen their trajectory until they orbit close to the receiver plates. The excitation also converts the original random phase of ions with a given  $m/z$  value into phase-coherent orbiting, allowing detectable image currents to be induced in the receiver plates. Hence, a sinusoidal signal with frequency  $\nu_{\text{ion}}$

and amplitude corresponding to the  $m/z$  value and the number of ions, respectively, is generated. When the trap contains ions of different  $m/z$  values, FT resolves the superposition of individual sinusoidal components into the individual  $\nu$  components ( $m/z$ ) and amplitudes.

The strong  $B$  field gives rise to a detectable  $\Delta\nu$  for ions with a  $\Delta m/z$  in the millimass range. This gives FT-MS an inherent potential for ultrahigh mass resolution and mass accuracy if the signal can be sampled over sufficient periods. However, collisions between the ions and neutrals from the residual vacuum, imperfect trapping fields, and sometimes space charge effects (too many ions in the cell) cause the phase coherence to vanish with time. Consequently, the signal becomes exponentially damped, and its decay rate determines the mass peak width and resolution. Hence, the resolution is simply increased by pumping the cell, optimizing of the trap voltages ( $V_{\text{trap}}$ ), or reducing the number of ions. The same actions also improve the sensitivity by optimizing the phase coherence and spread on the ion orbit radius after excitation. Unlike all other forms of MS, better mass resolution means better sensitivity in FT-MS.

The duration of the ionization step is not critical and can be in the millisecond range as long as no ions are added when excitation starts. Hence, unlike TOF-LMMS, FT-analyzers detect the prompt and postlaser component of the DI process. Ionization can be performed directly inside the cell or in an external ion source, in which case the ions are injected through an orifice in the temporarily grounded trapping plate. Differential pumping between the external ion source and the cell allows the sample chamber to be kept at a relatively high pressure without compromising the vacuum in the analyzer cell. Alternatively, a dual cell can be used in which the orifice of the common trap plate serves as the conductance limit for differential pumping. Transfer of ions from the high- to the low-pressure compartment occurs by grounding the middle trap plate, allowing the ion bunch to be equally distributed between the two cells.

All basic FT-MS configurations have been tried out for LMMS. The instrument at the IBM laboratories uses internal ionization in a single cell, with the sample behind an orifice in the trapping plate. The laser beam passes between the receiver and transmitter plates and impinges on the sample at an angle of less than  $45^\circ$  with a spot of  $5\text{--}8\text{ }\mu\text{m}$  diameter. The presence of the sample inside the high-vacuum analyzer cell excludes specimens containing volatile components, while the pump-down time after sample exchange is significant. Therefore, the FT-LMMS developed at the University of Metz (France) uses a dual cell and internal ionization. The laser beam is

directed through the two cells and strikes the sample perpendicularly to improve energy deposition. Ingenious Cassegrain optics around a refractive lens allow excimer and/or tunable dye beams to be used for LMMS experiments with and without laser postionization. Unfortunately, the orifice in the middle trap plate must be relatively large to allow the laser beam to pass. As a result, the pressure in the two cells is different by less than a factor of 100.

Apart from the pressure problem, internal ionization implies that the sample introduction and positioning system and the optics for laser focusing, sample viewing, and illumination are inside the narrow bore of the magnet. All devices must be remote controlled and made from materials compatible with the high  $B$  field. Hence, significant compromises on the specifications are unavoidable. Another fundamental limitation is regarding trapping. A cell with a  $V_{\text{trap}}$  value of 2 V only stores ions with a total energy ( $E_{\text{tot}}$ )  $< 2\text{ eV}$ .  $E_{\text{tot}}$  is the sum of the ion's  $E_{\text{kin}}$  (up to several electronvolts in laser DI) and the potential energy ( $E_{\text{pot}}$ ), defined by the electrostatic potential at the point of ionization. Hence, ions produced from a sample with a  $V_{\text{trap}}$  value of 2 V impact on the opposite trapping plate. Lowering the sample potential to keep  $E_{\text{pot}} + E_{\text{kin}} < 2\text{ eV}$  cause ions to undergo one reflection before they strike back on the sample. Trapping requires sufficient cooling with collisions with residual neutrals to occur within one back-and-forth trajectory. In practice, this implies a high cell pressure, detrimental to FT-MS performances.

Therefore, a FT-LMMS with a single cell and external ion source, shown in Figure 7, has been built at the University of Antwerp. The ionization chamber is far away from the magnet and freely accessible,

**Figure 7** Schematic diagram of the FT-LMMS with an external ion source developed at the University of Antwerp. (Adapted from Van Vaecck L, Van Roy W, Struyf H, Adams F, and Caravatti P (1993) Development of a laser microprobe Fourier transform mass spectrometer with external ion source. *Rapid Communications in Mass Spectrometry* 7: 323–331; Wiley.)

allowing adequate devices to be mounted for laser focusing to a spot size  $<5\text{ }\mu\text{m}$ , sample positioning, and viewing. Differential pumping of the transfer line allows the source and cell to be kept at  $10^{-6}$  and  $10^{-10}$  Torr, respectively. Dedicated ion optics producing static electrical fields guide ions with an initial emission angle of up to  $35^\circ$  to the cell. Furthermore, the potential of the sample and the selvedge can be freely tuned to keep  $E_{\text{ion}} = E_{\text{kin}} + E_{\text{pot}} < 2\text{ eV}$  for optimal trapping. As a result, the limit of detection (LOD) is as low as  $10^6$ – $10^7$  molecules, the mass resolution routinely exceeds 4 000 000 and 150 000 at  $m/z$  values of 56 and 1000, respectively, and the mass accuracy is better than 1 ppm.

## Analytical Figures of Merit

Local analysis of solids excludes the use of prior separation or enrichment steps. Hence, the specificity becomes as important as the sensitivity. The LOD essentially determines the minimal sample volume in which an analyte with a given concentration can be traced back. Specificity refers to a combination of information levels (elements, bonds, functional groups, MW, and/or structure), resolving power to overcome interferences, lateral resolution, and information depth. The last two parameters determine the scale on which compositional discontinuities can be observed.

The characterization of a thin layer or coating is the easiest case when its thickness exceeds the information depth. Additionally, minimal spectrometric resolution is required, while the analysed area can be enlarged to match the LOD. In contrast, analysis of microobjects on a substrate requires adequate sensitivity and sufficient specificity to distinguish between the analyte and substrate signals when the phase of interest is smaller than the lateral resolution and information depth. However, proper substrate selection makes this case less demanding than local inclusions in a complex heterogeneous matrix. Finally, buried analytes are the most difficult task. Sufficient information depth is required while the matrix contribution to the detected signals increases with the distance between the analyte phase and the surface.

Looking at the specificity in terms of the information level, LMMS and S-SIMS inherently rank high because full molecular information (i.e., MW + structural fragments) is obtained. In contrast, EPX-MA, X-ray and synchrotron radiation based methods are confined to elemental analysis, while the bond-specific information of X-ray photoelectron spectroscopy,  $\mu$ -infrared (IR), or Raman spectroscopy is insufficient for characterizing unknown mixtures.

The lateral resolution of LMMS is typically 1 and  $5\text{ }\mu\text{m}$  for (a)TOF- and FT-LMMS, respectively. The diffraction-limited spot size is 400 nm at  $\lambda = 200\text{ nm}$ . In S-SIMS, a full mass spectrum is typically recorded from an area between  $25 \times 25$  and  $250 \times 250\text{ }\mu\text{m}^2$ , while  $1$ – $5\text{ }\mu\text{m}$  is the minimal size of the features to be imaged with structural ions. Although a single laser shot erodes material to a depth of  $0.1$ – $1\text{ }\mu\text{m}$ , ions are only generated from the upper  $10$ – $50\text{ nm}$ . In contrast, the ion beam damage of the subsurface restricts the information depth of S-SIMS to one monolayer ( $0.1$ – $1\text{ nm}$ ). Both S-SIMS and LMMS have sufficient detection sensitivity to trace back the major components within one or a few monolayers. This brings the methods within the reach of nanoscale applications. The multilayer information depth in LMMS is an advantage in comparison with S-SIMS when accidental contaminants cover the surface of interest.

Only  $10^6$ – $10^7$  molecules are needed for detection of inorganic and organic analytes with average ionization yield in FT-LMMS with an external source. Under favorable conditions, an organic monolayer can be detected. Thanks to the sampling of the post-laser ionization, the LODs in high mass resolution FT-LMMS compare favorably with those of low mass resolution TOF-LMMS. Registration of a full mass spectrum from conversion layers on aluminum requires similar sample consumption in S-SIMS and FT-LMMS, yielding low and high mass resolution data, respectively. There are no limitations with respect to sample conductivity in LMMS, while charge build-up hampers the application of S-SIMS to dielectric coatings even as thin as a few micrometers.

So far, FT-LMMS is the only methodology for microanalysis with the specificity of high mass resolution. This makes the method superior by far to S-SIMS when it comes to the identification of unknowns. It also gives FT-LMMS a significant potential to deal with nanoscale analyte phases smaller than the spot.

Sampling the full ion production in FT-LMMS improves reproducibility in comparison with TOF-LMMS. Because the kinetics of the DI process does not affect the mass analysis any longer, FT-LMMS is applicable to analytes with higher MWs and more polar groups than TOF-LMMS. On the other hand, S-SIMS excels in generating structural ions at high  $m/z$  values from polymer materials, while LMMS tends to lead to pyrolysis.

Ion imaging is one of the attractive features of S-SIMS. Because the ionization in LMMS depends critically on exact focusing of the ionizing beam on the sample surface, mapping experiments are only feasible on very flat samples. The quantitative

capabilities of both methods are similar and depend on the availability of suitable reference samples for calibrating the signal as a function of the local composition. Cryofreezing of solutions and ultraslow lyophilization in vacuum yield adequate reference samples for determinations within typically 10%.

A major limitation is the inaccessibility of analytes buried deep under the surface. In this respect, non-destructive methods going from electron beam to spectroscopic techniques such as  $\mu$ -IR or  $\mu$ -Raman are more adequate but lack sensitivity for nanolayer detection.

## Selected Examples of Applications

### Biomedical and Biological Applications

The diffraction-limited spot of  $0.5\ \mu\text{m}$  allows TOF-LMMS in the transmission geometry to localize elements at the subcellular level. Tissue sections can be prepared using the common methods used for optical and electron microscopy. Cryotechniques are preferred because embedding of tissues in resin causes redistribution of mobile elements. Adequate calibration samples for heterogeneous tissue are a problem for quantitative work. Successful studies involve the localization of aluminum in bones of haemodialysis patients, accumulation of lead in kidneys due to chronic intoxication, incorporation of heavy metals from dental alloys in amalgam tattoos of the oral mucosa. Examples of speciation include the identification of hydroxy-apatite in the spheruliths of the Bowman's membrane from patients treated with high doses of cyclosporin. Also, the pathogenesis of aseptic loosening of joint prostheses has been related to the presence of zirconium oxide in granular foreign bodies of the surrounding tissue.

It has been anticipated that FT-LMMS with an external source would be inadequate for tissue research because of its spot size of  $5\ \mu\text{m}$  and reflection geometry hampering the visualization of sections. However, the composition and heterogeneity of tissues makes the analytical specificity of high mass resolution an invaluable asset. For instance, local analysis of foreign bodies in the inflamed tissue surrounding a titanium implant has allowed relatively simple mass spectra with prominent peaks at  $m/z$  values of 48 and 64 to be recorded. The inset in Figure 8 illustrates the detection of  $\text{TiO}^+$  at an  $m/z$  value of 64 with a mass resolution of 800 000, clearly sufficient to eliminate all isobaric interferences. The mass accuracy within 1 ppm ensures that the experimental  $m/z$  value is significant up to the fourth decimal place and excludes an alternative elemental composition. This leads to the unambiguous

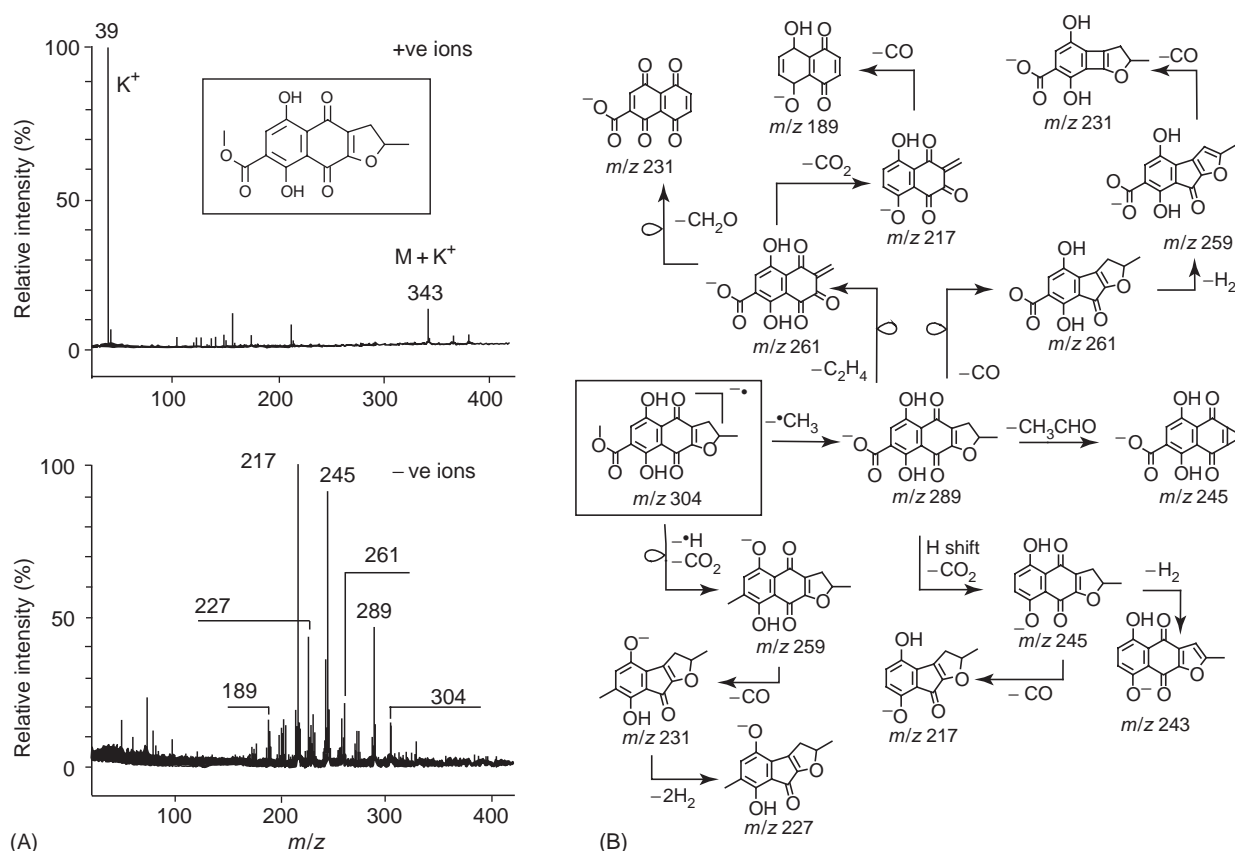

**Figure 8** Identification of foreign body cells in inflammatory tissue around a metal implant using FT-LMMS. The inset shows the high mass resolution trace of the  $^{48}\text{TiO}^+$  ions, offering sufficient separation and mass accuracy for unambiguous identification. (Reprinted from De Nollin S, Poels K, Van Vaeck L, *et al.* (1997) Molecular identification of foreign inclusions in inflammatory tissue surrounding metal implants by Fourier transform laser microprobe mass spectrometry. *Pathology Research and Practice* 193: 313–318; Gustav Fischer Verlag.)

identification of titanium oxide wear particles from the prosthesis.

Amongst biological applications using TOF-LMMS, the uptake of aluminum by fish in aquatic ecosystems subjected to acid rain has been studied. Use of the mass spectra of bacterial cultures as fingerprints has yielded screening methods for checking chemotherapy. The analytical specificity of high mass resolution FT-LMMS facilitates identification of organic substances in biological matrices. Figure 9 illustrates the results of an *in situ* analysis of the pigments responsible for sunlight interception and energy transfer in the apothecia of the microlichen *Haematomma ventosum*. The mass spectra from local spots with a diameter of  $5\ \mu\text{m}$  readily reveal the MW through the  $[\text{M}+\text{K}]^+$  and  $\text{M}^-$  ions at  $m/z$  values of 343 and 304, respectively. The detection of  $\text{M}^-$  confirms the occurrence of EI in LMMS. The high mass accuracy data in Table 1 are essential for the structural assignment of the numerous negative ion fragments and determination of the functional groups. As a result, FT-LMMS allows the time-consuming steps of isolation and subsequent high resolution MS to be performed while information on the local distribution is being obtained. Sample preparation only involves cutting raw biological material to dimensions not larger than  $1 \times 1 \times 1\ \text{cm}^3$ .

### Environmental Applications

The composition of single aerosol particles in the micrometer range is important for assessing their environmental health hazard and for studying the atmospheric chemistry of particle formation and transformation during atmospheric transport. Both

**Figure 9** *In situ* analysis of the pigment haemovantosin in the apothecia of a microlichen *Haematomma ventosum* using FT-LMMS. The structural assignment of the anions of major diagnostic interest is based on the high accuracy  $m/z$  data in Table 1. (Reprinted from Van Roy W, Mathey A, and Van Vaecck L (1996) *In-situ* analysis of lichen pigments by Fourier transform laser microprobe mass spectrometry with external ion source. *Rapid Communications in Mass Spectrometry* 10: 562–572; Wiley.)

issues make a distinction between the surface and bulk of individual particles desirable. In fact, TOF-LMMS is the first microprobe with sufficient sensitivity and specificity for molecular identification of inorganic and organic components in single aerosol particles collected through cascade impactor sampling. Successive recording of mass spectra at low laser power densities can be used to provide evidence of the presence of a nitrate shell covering a core of sodium chloride in a sea-salt aerosol. The detected adduct ions (cf. scheme in Figure 3) allow the chemical composition to be deduced with superior specificity in comparison with element detection using e.g., EPXMA. Furthermore, the information depth of  $\sim 1\mu m$  prevents the latter method from distinguishing between the composition of the core and shell. In contrast, EPXMA is superior to LMMS with respect to quantification and automated characterization of large particle populations.

The advent of aTOF-MS instruments that are capable of in-field experiments of online sampling and analysis has virtually annihilated the use of TOF-LMMS for aerosol research. Additionally, aTOF-MS

provides a major advantage by detecting both positive and negative ions from the same particle. Figure 10 shows the mass spectra of a single wood smoke particle that has yielded intense signals from structural fragments of (oxygenated) hydrocarbons. The ambient aerosol generates peaks from combustion related vanadium oxide and characteristic ions from ammonium nitrate. This information would not be available from one ion detection mode. Unlike TOF-LMMS, aTOF-MS can be automated for survey studies with high time resolution. The resulting huge data sets are processed using (multivariate) statistical procedures. On the other hand, aTOF-MS gives no information on the particle's morphology, which often includes interesting hints about its origin and formation. Also, the limited possibilities of fine-tuning the laser power density according to the particle type prevent distinction between the core and shell composition and cause many particles to generate insufficient spectral information. Ionization is improved by filling the source with a gaseous UV absorber, which coats the particle before irradiation.

**Table 1** Mass measurement of diagnostic ions detected from haemaventosin as shown in Figure 9

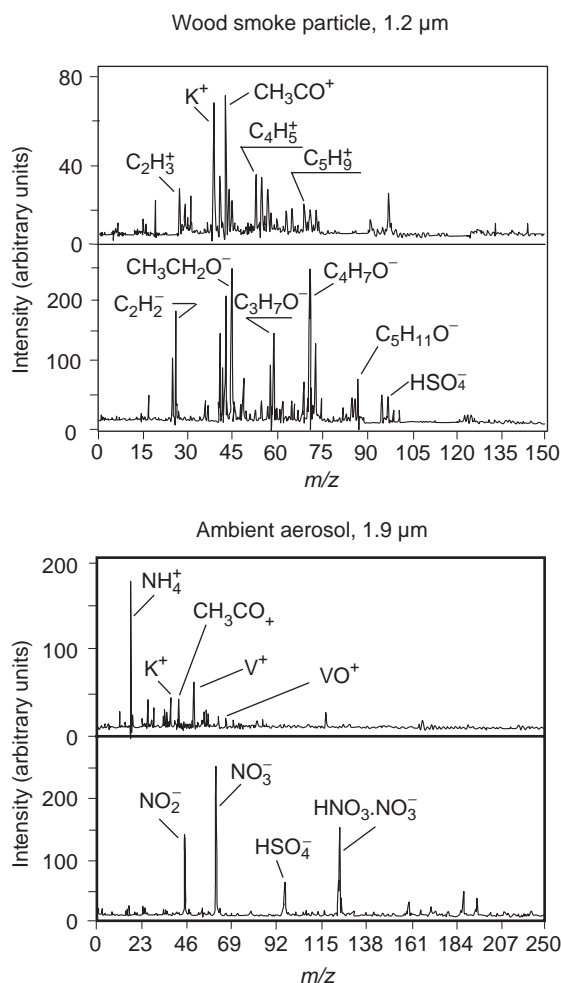

Experimental $m/z$	Elemental composition	Accuracy of $m/z$ (ppm)

### Industrial Materials and Troubleshooting Applications

The advantages of LMMS when compared with S-SIMS are the easy analysis of nonconducting samples, the increased diagnostic information due to the softer energy regime, and the capability of probing the molecular composition in the near-subsurface, i.e., under the upper monolayer, which often consists of accidental contaminants. As a result, LMMS is often applied to industrial processing faults.

Advanced metallurgical research has used TOF-LMMS to study casting or welding of new light alloys. The formation of borosilicates in the joints of oxide-dispersion-strengthened (ODS) superalloys has been related to metallic glass foils used for brazing. The presence of such heterogeneous phases in the joints of e.g., turbine engines can be detrimental under high-stress conditions. The discoloration of steel can be due to the deposition of unwanted species or to light interference by a thin homogeneous oxide layer. Unlike Auger electron spectroscopy, TOF-LMMS distinguishes between the two causes. Other examples involve the identification of surface impurities that prevent subsequent hardening or anticorrosion coatings from adhering. Paint defects become apparent only when the different lacquer layers have been already applied. In that case, successive laser shots

**Figure 10** Positive and negative ion mass spectra detected using aTOF-MS from a single wood smoke particle (top) and atmospheric aerosol sampled in Riverside, CA. (Reprinted from Gard E, Mayer JE, Morrical BD, *et al.* (1997) Real-time analysis of individual atmospheric aerosol particles: design and performances of a portable aTOF-MS. *Analytical Chemistry* 69: 4083–4091; American Chemical Society.)

allow buried contamination to be exposed for analysis. Unlike S-SIMS, laser erosion is nondestructive to molecular information, and structural ions have been recorded from fragments of polyethyleneterephthalate (PET) gloves left by coachbuilders on bare metal.

Although LMMS is limited in the characterization of polymers, it excels in the study of local inclusions compromising material performances. For instance, poorly dispersed accelerators and local accumulation of metals from corroded reactor or extruder walls have been traced back using TOF-LMMS. The dispersion of magnetic material inside the PET matrix of faulty floppy disks has been studied using external source FT-LMMS. Simultaneous detection of the inorganic and organic components has allowed disk failure to be correlated to compositional anomalies.

Easy speciation and isotope detection have been identified as playing important roles in optimizing the production of superconducting  $\text{Nb}_3\text{Sn}$  wires by heating a composite of bronze and niobium filaments. Application of TOF-LMMS has provided evidence of the out-diffusion and accumulation of phosphorous, inhibiting  $\text{Nb}_3\text{Sn}$  formation when tin diffuses inward. The preferential incorporation of the lower tin isotopes in the  $\text{Nb}_3\text{Sn}$  layer has confirmed the process to be driven by diffusion. The semiconductor industry has used TOF-LMMS to verify the lateral diffusion of dopants, e.g., boron in tantalum and cobalt silicide runners only  $3\text{ }\mu\text{m}$  wide. Another application is the identification of microscopic residues left on integrated circuits after removal of the photoresist.

The increased identification power due to high mass resolution in FT-LMMS significantly enlarges the range of troubleshooting applications in comparison with TOF-LMMS. In particular, anomalies in the extremely well-controlled production of pharmaceuticals and fine chemicals require completely unexpected compounds to be identified. Quality control procedures nowadays require the reason for only a few microscopic particles in complex formulations to be traced back. Application of FT-LMMS to a few micrometer-size particles has allowed specific causes to be pinpointed, such as components from the piston and ceramic seal pointing to a faulty high pressure liquid chromatography pump, polyimide fragments indicating wear of the belt driving a stirrer, and an organic salt pointing to an incomplete washing step.

Figure 11 shows mass spectra taken from the organic additive on the surface of a rolled aluminum plate, using FT-LMMS with an external ion source. The mass resolution easily exceeds 100 000, and the mass accuracy (Table 2) is within 0.1–1 ppm. The specific problem studied here relates to the deposition and interaction of organic additives from the lubricating emulsion used in the aluminum hot rolling process. Irreversible binding of organic additives to the aluminum at high temperatures and pressures causes microscopic defects in the subsequently applied anodization layer or coating. The positive ion mass spectra contain several signals not found with the pure additive (framed structures in Figure 11). The elemental composition derived from high mass accuracy data indicates the presence of  $\text{Al}^{3+}$  together with two anionic functionalities. These ions must originate from ion pairs that exist already in the solid state before ionization since the laser only generates  $\text{Al}^+$  to form adducts in the selvage. In this example, FT-LMMS has been used to achieve one of the most difficult tasks in MS, namely the detection

**Figure 11** Identification of the interaction products between the triethanolamine oleate additive of a lubricating emulsion and rolled aluminum. Top: positive ion mass spectrum recorded using FT-LMMS with an external ion source. Bottom: structural assignment of the ions of major diagnostic interest. The corresponding high accuracy  $m/z$  data are listed in Table 2. The framed structures are indicative of the binding of the additive to aluminum. # ATOMIC SPECTROMETRY

## Overview

**J A Holcombe**, University of Texas at Austin, Austin, TX, USA

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Traditionally, analytical atomic spectroscopy implied the use of electromagnetic radiation in the ultraviolet (~200–350 nm) and visible (~350–800 nm) region of the spectra for qualitative and quantitative analysis. With the use of some of the same sources to produce ions for detection using mass spectrometry, the term often encompasses the area of elemental mass spectroscopy. In this section the focus will remain on optical techniques.

Atomic spectroscopists are concerned with the energy states of the atom or ion under study. These energy states can be seen diagrammatically in a term

(or Grotian) diagram, as shown in **Figure 1** for Na. These are the energy states for the isolated atom in the gas state. Molecules such as NaCl<sub>(g)</sub> have their own unique set of allowable energy states but have little relationship to the atomic spectral states. As a consequence, in order to use atomic spectroscopy to conduct elemental analysis on a sample, the species of interest (the analyte) must be converted to gaseous atoms using a source (flame, plasma, etc.). It should also be noted that the energy states are entirely different for the free atom and its ion. As a result, if we are to determine the atom concentration we need to minimize the extent of ionization if monitoring a neutral atom line, maximize ionization if monitoring an ion line or, at the very least, keep the degree of ionization constant from one sample to the next. This way the number of atoms or ions detected in our source remains proportional to the analyte concentration in the sample.

Three general types of experiment can be used in atomic spectroscopy: emission, absorption, and fluorescence (**Figure 2**). The 'atom cell' is where free gaseous atoms are generated (e.g., a flame). The

intensity of the radiation detected ( $I$ ) is measured and used to determine ultimately the analyte concentration in the sample, which is generally a solution.

**Figure 1** Term diagram for sodium showing location of various atomic states of the neutral atom. The vertically oriented lines denote some of the allowable transitions that could occur that give rise to spectral lines. The two transitions that are annotated with the emission (or absorption) wavelengths of 589.59 and 589.00 nm are the resonance lines that appear in the yellow region of the spectra and are often termed as the Na D lines.

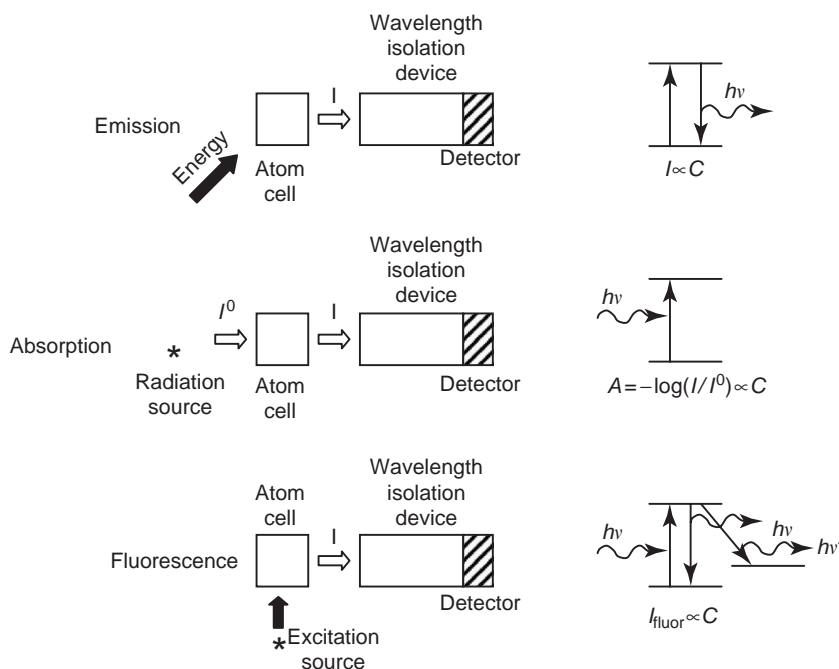

## Fundamentals of Atomic Spectrometry

### Electronic Transitions

Figure 1 suggests that a number of transitions to various energy states could take place in the atom. In emission spectroscopy, the excited states are generally populated by collisional processes (e.g., heat); and when they relax ('fall down' to a lower energy state), they can lose the gain in internal energy either radiatively or nonradiatively. In spectroscopy, we are interested in radiative relaxation processes in which the wavelength of the emitted radiation is related to the transition energy,  $E_{\text{trans}}$  (Figure 3),

$$E_{\text{trans}} = hc/\lambda \quad [1]$$

where  $h$  is Planck's constant ( $6.626 \times 10^{-34}$  J s),  $c$  is the velocity of light ( $2.99 \times 10^8$  m s $^{-1}$ ), and  $\lambda$  is the wavelength in meters. Thus, a number of spectral lines can exist for any given element, depending on the extent of population of the various excited states. However, not all transitions are quantum mechanically allowed, thus reducing some of the spectral complexity. For most atomic spectroscopy applications, the primary transitions that provide the maximum sensitivity involve the ground state and are referred to as resonance transitions, and the resulting spectral lines referred to as resonance lines. In most sources, these are the primary lines used for analysis.

**Figure 2** Schematic diagram of three dominant processes (emission, absorption, and fluorescence) that can be used for spectrochemical analysis.

**Figure 3** Radiative relaxation processes that could occur from population of an excited state that has an excitation level of  $E_{\text{ex}}$  above the ground state. The transition energies,  $E_{\text{trans}}$ , of  $E_1$  and  $E_2$  give rise to emission lines at  $\lambda_1$  and  $\lambda_2$ , respectively.

While Figures 1 and 3 suggest the lines are of a single wavelength, each line has a finite width. The natural line width is as narrow as a spectral line can be and is governed by Heisenberg's uncertainty principle,  $\Delta E = h/(2\pi\tau)$ , where  $\Delta E$  is the uncertainty in the exact location of the excited state and  $\tau$  is the excited state lifetime, which is  $\sim 1$  ns for many electronic transitions of atoms. For a 300 nm line and  $\tau \sim 1$  ns, this predicts a natural line width of  $\sim 0.05$  pm. Line widths of most sources are broader than this because of collisional (i.e., pressure) or Doppler broadening mechanisms. For sources at 1 atm pressure and a few thousand degrees, both these broadening mechanisms produce line widths in the range of a few picometres or about a hundred times larger than the natural line width. The very narrow lines (even with broadening) permit unique wavelength assignments to specific elements and provide a degree of selectivity found in few other analytical techniques.

### Population of States

Most thermal sources used in atomic spectrometry provide temperatures in the range 1500–7000°C. Even at extreme temperatures, a majority of the neutral atoms exist in the ground state. Table 1 provides some indication of the temperature-dependent population of the first excited state for Na, which is relatively easily populated. The table also shows the population of the first excited state of Zn, whose transition energy, in contrast, is more than twice that of Na. At the higher temperatures, ionization can become appreciable and a majority of the analyte may exist as the ionized species, although, those sodium species still present as neutral atoms will still exhibit the relative populations shown in Table 1.

The fractional population of excited states in a system under local thermodynamic equilibrium (LTE) can be determined using Boltzmann's equation,

$$\frac{N^*}{N_T} = \frac{g^* e^{-E^*/kT}}{Z(T)} = \frac{g^* e^{-E^*/kT}}{\int g_i e^{-E_i/kT}} \quad [2]$$

**Table 1** Relative population of the first excited states of sodium and zinc at various temperatures

Temperature (K)	Na (589.6 nm)	Zn (213.9 nm)
1000	$2.6 \times 10^{-11}$	$2.3 \times 10^{-29}$
1500	$8.9 \times 10^{-8}$	$1.2 \times 10^{-19}$
2000	$5.1 \times 10^{-6}$	$8.3 \times 10^{-15}$
2500	$5.9 \times 10^{-5}$	$6.8 \times 10^{-12}$
3000	$3.0 \times 10^{-4}$	$5.9 \times 10^{-10}$
3500	$9.5 \times 10^{-4}$	$1.4 \times 10^{-8}$
4000	$2.3 \times 10^{-3}$	$1.6 \times 10^{-7}$
4500	$4.4 \times 10^{-3}$	$1.0 \times 10^{-6}$
5000	$7.5 \times 10^{-3}$	$4.5 \times 10^{-6}$
5500	$1.2 \times 10^{-2}$	$1.5 \times 10^{-5}$
6000	$1.6 \times 10^{-2}$	$4.2 \times 10^{-5}$
6500	$2.2 \times 10^{-2}$	$9.9 \times 10^{-5}$
7000	$2.8 \times 10^{-2}$	$2.1 \times 10^{-4}$

where  $N^*$  and  $N_T$  are the number densities (e.g., atoms  $\text{cm}^{-3}$ ) of atoms in a given excited state and all the atoms, respectively;  $g$  is the statistical weight;  $E^*$  is the excitation energy (energy above the ground state – see also Figure 3);  $k$  is Boltzmann's constant ( $1.38 \times 10^{-23} \text{ J K}^{-1}$ ); and  $T$  is the temperature in Kelvin.  $Z(T)$  is the partition function, which basically represents the sum of the fractional populations of all other states in the atom. The numerical value of  $Z(T)$  can be found in tables. Since most of the atoms are located in the ground state, eqn [2] can be approximated by

$$\frac{N^*}{N_T} \approx \frac{N^*}{N^0} = \frac{g^* e^{-E^*/kT}}{g^0} \quad [3]$$

where  $N^0$  is the population of the ground state and  $g^0$  is the statistical weight of the ground state.

### Ionization

The extent of ionization depends on the element, the temperature, and the free electron density. It varies from source to source. Ionization can be written as an equilibrium process:

Given no other dominant source of electrons, the degree of ionization will increase as the number density (or partial pressure) of the analyte in the source decreases. The extent of ionization also increases as the ionization potential of the element decreases. The degree of ionization can be calculated using Saha's equation.

Excessive ionization can reduce the atomic spectroscopy signal from the neutral atom, although accurate quantitation can still be conducted as long as the degree of ionization remains constant for all samples and standards. In some high-temperature sources, ionization is sufficiently large for ions to be

the dominant species, and the ion resonance line is used for analysis.

### Interferences

The term 'interference' is applied to any source or event that causes the signal for a given amount of analyte to be bigger or smaller than would be predicted from the calibration curve. These are often subdivided into chemical, ionization, and spectral interferences. In brief, there is an expectation that the atom density in an atomic spectroscopic source (and the relative population in an excited state for emission techniques) remains proportional to the elemental concentration in the sample. Anything in the source or sample that invalidates this assumption causes an interference.

## Basic Instrumentation

### Spectrometers

Since a wavelength characteristic of the element(s) of interest must be isolated, a dispersive device must be included. Generally gratings are used in

spectrometers to accomplish this function. The 'size' (i.e., focal length of the mirrors) combined with the density of rulings on the grating or mounting configuration of the optical components govern the resolution available. A higher resolution is needed when the analyte line must be isolated from a very large number of lines or when multiple detectors are used and there is subsequent need for physical space to place the detectors in the focal plane of the spectrometer. **Figure 4** illustrates a simple dispersive device based on a diffraction grating. The term 'spectrometer' is generic and applies to all types of dispersive-type instruments. 'Spectrophotometer' generally refers to an instrument where comparison measurements are made, such as in absorption spectroscopy. When a single exit slit exists and the grating is rotated to select the wavelength, the device is called a monochromator. With multiple exit slits and multiple detectors, the term 'direct reader' or 'polychromator' is often used.

In some instances where the spectral isolation demands are minimal, simple interference filters can be used in place of a dispersive-type instrument. In these cases, the term 'filter photometer' rather than 'spectrometer' is employed.

**Figure 4** Schematic diagram of one configuration ('mount') for a reflection grating monochromator. This particular arrangement of mirrors and grating is relatively common and referred to as a Czerny–Turner mount. The dashed and solid lines leaving the grating represent shorter and longer wavelengths, respectively, that are angularly separated after diffraction by the grating has occurred. Simple front-surfaced plane mirrors (M) serve only to 'bend the beam'. The detector shown in this diagram is a photomultiplier (PMT).

## Detectors

While photographic film was traditionally used as a detector, various types of photoelectric detectors have replaced it. The photomultiplier (PMT) is a commonly used, sensitive detector where photons striking the photocathode cause the ejection of an electron if the photon energy can overcome the work function of the material used in fabricating the photocathode. The probability of a photon producing a photoelectron from the cathode is termed the quantum efficiency, which is dependent on the cathode material and wavelength. A quantum efficiency of 10% is typical. This photoelectron is electrically directed and accelerated to the first dynode where multiple (typically two to six) secondary electrons are ejected and accelerated to the next dynode. At each successive dynode a cascade of electrons strikes the next dynode. A typical PMT has approximately 9–16 dynodes. Ultimately, a large number of electrons are produced and are collected at the anode. Thus, a measurable current can be detected from a single photon. Gains of  $10^5$ – $10^8$  (electrons per photon) are not uncommon.

Arrays of solid-state detectors are becoming increasingly popular. These include linear photodiode arrays and various ‘panoramic’ or two-dimensional detector arrays such as charge coupled devices (CCDs) and charge injection devices (CIDs). These detectors can monitor multiple wavelengths simultaneously and provide varying degrees of time resolution when needed. While they have minimal gain compared with the PMT, they do have a higher quantum efficiency, i.e., the number of electron/hole pairs produced per incident photon in the solid-state devices is higher than the number of photoelectrons produced per photon incident on the photocathode of a PMT.

## Sample Introduction

For many of the techniques, a nebulizer is the primary means of producing very small droplets of a solution sample or standard that is transported to a high-temperature source where it undergoes desolvation, vaporization, and atomization. While a range of droplet sizes is generated, some means of size discrimination is present to insure that larger droplets (greater than  $\sim 2.5\ \mu\text{m}$ ) are kept from the thermal source. Nebulizers come in a variety of different designs, often serving slightly different functions. Some require very small volume uptake rates (e.g., microconcentric and direct injection nebulizers), others are more efficient at producing small droplets (e.g., ultrasonic nebulizers), and still others are capable of handling viscous and

particle-laden solutions (e.g., Babington and cross-flow nebulizers).

A variety of other approaches are also used including discrete micropipetting of solutions, production of gaseous hydrides, ablation of solid materials using a laser or electrical spark, and even reduction and direct use of metal vapor in the headspace above a liquid such as in the case of Hg determinations. In addition to ablation, which samples a relatively large mass of material from a solid ( $\sim 1\ \mu\text{g}$  per pulse), sputtering processes (e.g., ion beams and various low-pressure discharge processes) have also been used. In general, any approach that permits the introduction of a vapor or small aerosol particles into a source from a solid, liquid, or solution could be considered as a possibility for conducting quantitative analytical atomic spectrometry. Analysis of gaseous samples by direct introduction, of course, can also be done.

## Atomic Emission

### Fundamentals

The primary objective is to have the analyte emit radiation in proportion to the concentration in the sample being analyzed. Resonance lines are typically monitored for maximum sensitivity. For thermal sources in LTE, Boltzmann’s equation (eqn [2]) governs the relative population of the excited states. The intensity of the emission from radiative relaxation from this state is proportional to this population, the atom density in the source being monitored, and a factor that indicates the strength of the emission. This last factor is often referred to as the oscillator strength (which is also proportional to Einstein’s A coefficient for spontaneous emission) and gives an indication of the probability of radiative relaxation from an excited state. The oscillator strength is small for ‘disallowed’ transitions, such as those where an apparent change of spin state in the atom occurs. As a consequence, a low-lying excited state whose population appears to be high may emit a weak spectral line because of a small oscillator strength.

Sources tend to deviate from LTE as the rate of fluctuation in energy input into the source increases, such as in an electrical discharge with a high-frequency electric field used for excitation or when the source is at a reduced pressure and the collision frequency is too low to distribute the energy amongst the various energy modes, e.g., electronic excitation energies versus translational energy distribution. A source at LTE will have all its ‘temperatures’ at the same value. A combustion flame is an example of an

LTE source, while a low-pressure discharge lamp (such as a hollow cathode lamp (HCL)) is not. Similarly, there are some who argue that the inductively coupled plasma (ICP) is not at LTE, possibly as a consequence of the rapid oscillatory energy delivery to the plasma in the megahertz frequency range.

## Sources

The classic source is a chemical combustion flame such as an acetylene–air flame. **Table 2** shows flame temperatures for various fuels and oxidants. In today's instruments, acetylene–air and acetylene–nitrous oxide are the most common fuel–oxidant mixtures. In general, flames are considered relatively low-temperature sources (2000–3000°C) and have their greatest utility in determination of alkali metals and alkaline earth metals. (The cyanogen/oxygen flame shown in the table is considered an 'exotic flame' and is rarely used in analysis both because of the toxicity of the fuel as well as the high production rate of CO as a combustion byproduct.)

Electrical discharges were among the first moderate- to high-temperature sources and included arcs (DC currents of 1–20 A between solid electrodes) and sparks (repetitive, oscillating AC, or DC discharges resulting from discharging a capacitor charged to several thousand volts between two electrodes). Direct current plasmas (DCPs) were also popular for a while. Simply stated, a DCP is an arc where the metal electrodes are positioned at a 45° angle to each other and aspirated solutions are injected into the 'V' formed by the plasma and the upward streaming inert sheath gas. While sparks still entertain an enthusiastic audience in the metallurgical industry, arcs, DCPs, and sparks are generally absent from most analytical labs today.

The 'high-temperature', analytical workhorse for emission spectroscopy is the inductively coupled plasma (ICP). Inducing a current in a flowing stream of ionized Ar gas produces this electrodeless discharge. The rapid movement of electrons caused by

the megahertz frequency in the radio frequency (RF) generator sustains the plasma through secondary ionization of the Ar gas via electron collisions:

The typical power usage of these excitation sources is 1–3 kW. Although they are well sealed to insure no RF leakage, they have nonetheless been assigned two bands (27 and 40 MHz) by the Federal Communication Commission in the US and similar regulatory agencies in other countries. This is done since they employ power levels that one might expect from a medium-sized radio station! ICP temperatures are generally reported to be in the 6000–8000°C range, with temperatures as high as 10 000°C having been reported. While lower-temperature sources (e.g., flames) contain a number of molecular species, many of which emit characteristic bands that block regions of the spectra, the ICP temperatures are sufficient to atomize and ionize nearly all material within the discharge. The spectral features are line spectra of atoms and ions.

In glow discharges a milliamper discharge is established between one electrode and the conducting sample in a low-pressure, inert atmosphere. This gentle discharge produces line-rich spectra with a high degree of excitation and ionization but very low kinetic temperatures (a non-LTE source). Other types of discharges include microwave-induced plasmas (MIPs) that have been operated both at reduced and atmospheric pressures. Generally, an MIP is operated with only a few hundred watts of power and, as a consequence, often does not have the energy needed to vaporize large, condensed-phase particles (e.g., liquid aerosol particles from nebulizers), although some literature reports on success with such samples in addition to direct introduction of gaseous, analyte-containing molecules. The degree of molecular dissociation to form atoms and ions is again high in this type of source, and the spectrum is line rich.

## Spectrometers and Detectors

Simple, low-dispersion monochromators or even interference filters are used for most flame emission applications since few *atomic line* spectral interferences are expected as a result of the limited population of the higher-lying excited states. For high-temperature sources such as ICPs, higher-dispersion spectrometers are typically used. Instruments set up to do simultaneous multielemental analysis can use direct readers with PMT detection. However, most modern detections systems for this type of source for simultaneous multielemental analysis employ a high-dispersion echelle grating spectrometer and an array detector such as a CCD or CID.

**Table 2** Flame temperatures for various fuel/oxidant combinations<sup>a</sup>

Fuel	Oxidant	Temperature (K)
Propane	Air	2300
Hydrogen	Air	2400
Acetylene	Air	2700
Hydrogen	Oxygen	2900
Acetylene	Nitrous oxide	3000
Cyanogen	Oxygen	5000

<sup>a</sup> Temperatures can vary slightly from the values given depending on the fuel:oxidant ratio used. Acetylene-based flames are the most commonly used for analytical spectroscopy.

Moderate- to high-resolution monochromators equipped with computer-controlled scanning and PMT detection is another way of obtaining multi-elemental analysis. In these cases the intensity at the first wavelength of interest is measured, followed by a rapid slewing to the next wavelength region and a slow scan over the second spectral line, slewing to the third line, scanning the third line, etc. The instrumentation is often referred to as a slew-scan monochromator.

## Analysis

As noted earlier, flame emission has its biggest niche in analysis of the alkali metals and alkaline earth metals. As a result, they are often found in such areas as clinical laboratories, where such elements as Na and K are of routine interest. The technique is quite mature, and many proven methods for a variety of analyte-matrix combinations are available.

ICP optical emission spectrometry (ICP-OES) is also well established, and numerous procedures exist for a host of complex sample types. It is not uncommon to employ internal standards for ICP-OES. This is particularly useful to compensate partially for variations in sample delivery rate and, to a lesser extent, for small fluctuations in the plasma. The technique is relatively free of chemical interferences, and most spectral interferences can be corrected for. In addition to providing parts per billion to parts per million limits of detection for most of the periodic table with precisions of a few per cent or less, ICP-OES can also provide five to six orders of magnitude in analytical dynamic range.

Standard additions in lieu of simple aqueous standards and a calibration curve may be used in instances of very complex matrices. When the approach is used by adding a small volume of a standard to the unknown solution in the course of analysis to validate the legitimacy of the slope of the calibration curve (i.e., the sensitivity), the term 'spike' is applied.

## Atomic Absorption

### Fundamentals

Atomic absorption (AA) is based on 'stimulated' absorption since the number of photons absorbed is dependent on the photon flux of the incident light. However, the fraction of the light absorbed is relatively independent of source intensity until the incident intensity reaches extremely high levels and begins to populate substantially the excited state. At that point the probability of absorbing a photon

is no longer significant relative to having a photon re-mitted by stimulated emission from the high-lying excited state. Under the normal, lower light level operating mode, the relationship between absorbance and concentration is similar to the Beer-Lambert law used for solution absorption, with minor modification of terms:

$$A = k_{\text{abs}} \times C \quad [6]$$

where  $k_{\text{abs}}$  is the absorption coefficient and  $C$  is the analyte concentration; as in solution spectrophotometry, the linear relationship holds as long as a number of assumptions hold. In particular, it must be assumed that  $k_{\text{abs}}$  is singularly valued over the wavelength interval being monitored, i.e., the width of the incident line is much narrower than the width of the absorbing wavelength. When this is not the case, curvature of the calibration curve ( $A$  versus  $C$ ) results and is most pronounced at larger absorbance values. While the line widths of light sources typically used in AA (e.g., discharge lamps or HCLs) are narrow, so is the absorbing line width, and linearity is not assured over a large range of concentrations. Similar nonlinear responses can be observed if the spectrometer bandpass encompasses more than one spectral line from the incident light source or if stray light in the spectrometer is significant.

Since the typical discharge light source usually derives its spectrum from the metal that is used in fabricating the source, AA provides a high degree of elemental selectivity. This selectivity and general absence of spectral interferences from other atomic species is further enhanced by the requirement that the absorbing state must be populated, which means that resonance transitions originating in the ground state are the only absorbing lines that show any measurable absorbance. Similarly, Boltzmann's distribution shows that for most elements and most AA 'atomic cells', 99 + % of the atoms are in the ground electronic state, and this condition does not change with relatively wide variations in temperature. This places much less stringent requirements than for emission spectroscopy on the source temperature. In general, the primary role of the energy in an AA atom cell is to insure efficient – or at least consistent – free atom production.

### Sources

AA requires two 'sources': one in which free atoms are produced or the sample is 'atomized' (e.g., flame) and one that produces the radiation that is to be absorbed by these atoms. To avoid confusion, these will be referred to as 'atomizer' and 'radiation source' in the following discussion.

**Atomizer** As noted above, the primary function of the atomizer is to make isolated atoms in the gas phase efficiently. There is no need for excitation, and it would be undesirable, generally, to ionize the analyte.

In the case where the sample is introduced as a solution aerosol, the atomization source must evaporate the solvent, vaporize the resulting salt particles, and dissociate any analyte-containing molecules – tasks that are similarly required when wet aerosols are used in emission spectroscopy. Since collisions with high-temperature gases are the most efficient means of accomplishing the first two tasks, thermal sources such as flames are typically used (e.g., flame AA).

Small tube furnaces also accomplish these tasks efficiently by drying out a discretely deposited solution sample ( $\sim 10\text{--}20\mu\text{l}$ ) that is placed on the surface of the tube. For some samples where the analyte is not prematurely vaporized, some of the desolvated salt can be thermally decomposed (and sometimes vaporized) during a ‘char’ or ‘thermal pretreatment’ cycle in the furnace. This effectively eliminates some of the matrix prior to the ‘atomization’ heating cycle when the analyte vapor is introduced into the optical path. These atomizers are often referred to as graphite furnaces or more generally as electrothermal atomizers (ETAs). They exhibit an advantage over flames because the atoms have a significantly longer residence time in the absorbing volume. This  $\sim 100$ -fold increase yields an  $\sim 100$ -fold improvement in sensitivity. Additionally, the entire sample dosed into the ETA has the potential of being introduced into the observation volume. In contrast, the nebulizer and aerosol delivery system in a flame are only  $\sim 5\%$  efficient. Thus, even at a  $5\text{ ml min}^{-1}$  aspiration rate, the flame receives the sample at only  $\sim 5\mu\text{s}^{-1}$ , in contrast to the ETA, where  $20\mu\text{l}$  is introduced, albeit as a transient pulse.

Another common atomizer is a simple heated quartz tube into which a gaseous metal hydride is introduced, generally produced by reaction of the sample with a strong reducing agent such as sodium borohydride ( $\text{Na}_2\text{BH}_4$ ). These volatile metal hydrides are relatively labile and can be dissociated at relatively low temperatures to yield the free metal. In addition to a quartz tube, the hydride generation technique can also be used by introducing the hydride directly into a flame. While applicable to a number of metals, hydride generation finds its most common use with the semimetals (e.g., Se, As, Te, In, Bi) and a few others (e.g., Pb, Sn, Sb, Cd).

Mercury is unique since its elemental form has a moderately high vapor pressure even at room temperature. Thus, by adding a reducing agent to a

sample and purging the solution with a stream of gas (Ar or  $\text{N}_2$ ), the free  $\text{Hg}_{(\text{g})}$  can be pumped through a quartz tube with optical windows and absorbance measurements made. This is often referred to as a cold vapor technique and is almost exclusively applied to Hg determinations where parts per trillion detection limits have been reported.

**Radiation sources** The most common radiation source used with AA is a HCL, which consists of a tubular-shaped cathode made of the metal of interest and a simple anode. A milliamp DC discharge is established between these electrodes in a low-pressure noble gas environment. The discharge results in a very line-rich spectrum of the cathode material. Electrodeless discharge lamps (EDLs) are brighter and require a microwave power supply. For elements whose HCL lines are weak, EDLs are often the lamps of choice.

There are two other sources worth noting, although they are currently used in a very small fraction of the instruments employed. Continuum sources can be used if their intensity is sufficient to minimize noise levels and if the spectrometer has sufficient dispersion to make the spectral bandpass comparable with the absorbing line width. While feasibility has been demonstrated in research laboratories, there currently is no commercial instrument available. At the other extreme, using a very bright, stable source with a narrow line width has produced viable absorbance readings that are two to three orders of magnitude below those available with HCLs and EDLs. The source that provides this detection enhancement is a tunable diode laser.

### Spectrometers and Detectors

The spectrometer is generally a monochromator of moderate to low resolution since it is only necessary, in most cases, to isolate the resonance line of interest from the other atomic lines in an HCL or EDL. The PMT is typically used for detection.

The optics are generally moderately complex and of a double-beam design using modulated lamps with a chopper to measure all signals needed to calculate absorbances while accounting for lamp drift, emission from the atomizer, background absorbance/scatter, and any drift or dark current in the detector.

### Analysis

AA is useful for most of metals and semimetals, with flames and ETAs providing parts per million and low parts per billion limits of detection, respectively. Both are relatively mature techniques, with a variety of methods for handling various analyte–matrix

combinations. Generally, the ETA has to accommodate complex background signals that can arise from the matrix. As a result, background correction techniques are available on all commercial instruments.

AA is generally considered a 'single element technique' where one analyte is determined at a time. However, high degrees of automation make it relatively simple to deal with a large number of samples, standards, and analyte elements with minimal to no operator attention. There are also some instruments now available that permit a limited number of elements (four to eight) to be determined simultaneously, and a system using a continuum source and high-dispersion spectrometer with array detection can provide true simultaneous multielement capabilities.

## Atomic Fluorescence

### Fundamentals

Similar to AA in its requirements for operation, atomic fluorescence (AF) requires free gaseous atoms in the ground state. Population of an excited state is accomplished by absorption at a wavelength corresponding to a resonance transition. Once in the excited state, it can radiatively relax – like atomic emission – and the intensity of this fluorescence is used for quantitation.

Both resonance and nonresonance fluorescence can be used. The emitted resonance fluorescence is shown in **Figure 2** as  $h\nu$  and the nonresonance fluorescence as  $h\nu'$ . Nonresonance fluorescence is often preferred since the detected wavelength is different from the excitation wavelength, and the scatter of the exciting beam in the atomizer can be more easily excluded by the monochromator. Unlike AA, where a small decrease in intensity (which has fluctuations or noise inherent to it) is the key to determining the limits of detection (LODs), AF searches for the appearance of photons against a 'dark background'. This has the potential of yielding significantly improved LODs.

In contrast to AA, a brighter light source will yield better sensitivities since the signal is proportional to the concentration of the excited state atoms. If the intensity of the source is sufficient (e.g., laser radiation), the population of the excited state can be brought to saturation. In addition to maximizing the fluorescence intensity, this also makes the fluorescent intensity insensitive to small fluctuations in the excitation source intensity.

As with emission spectroscopy, anything present in the sample that alters the degree of radiative relaxation will impact the signal and result in 'interference effects'. In AF, the 'term quantum yield' is used to

describe the fraction of the excited state that relaxes radiatively. A good absorber with a high quantum yield should provide optimal sensitivity.

### Sources

**Atomizers** The same requirements that exist for AA also exist for AF. Consequently, similar sources have been used. However, since the long path length needed with AA to maximize the sensitivity is not needed with AF, ICPs and more circular flames have been used in place of the traditional chemical combustion flame with a slot burner. ETAs have also been used to enhance the sensitivity for AF as has been done for AA, and the resulting LODs are some of the best for the atomic spectroscopic suite of techniques when combining an ETA with laser excitation.

**Radiation sources** As in AA, line sources are typically used, although high-intensity sources are much more critical in AF. Boosted HCLs and EDLs have been employed. However, tunable lasers certainly provide the optimal sensitivity, i.e., laser excited atomic fluorescence spectrometry.

### Spectrometers and Detectors

Since the fluorescence spectrum should be relatively simple because of the selective radiative excitation of only the analyte, monochromators with only limited resolution are needed. Detectors that can be used in a photon counting mode (i.e., can detect individual photons) optimize the LODs. For this reason, PMTs are commonplace in AF.

### Analysis

Although research papers related to AF continue to appear, practical applications are less common than for the other techniques. As mentioned previously, when combined with an efficient atom cell (e.g., ETA) and a bright light source (e.g., laser), AF can provide exceedingly low detection limits.

This overview on analytical atomic spectrometry touches on the basics of three dominant methods of conducting optical spectroscopy for the purposes of qualitative and quantitative elemental analysis. There are a number of variations in sources, atom cells, dispersive devices, etc. that have not been discussed. As an example, laser-induced breakdown spectroscopy employs a high-intensity laser to ablate samples where the extreme radiant energy also produces a plasma that ultimately produces electronic excitation of the ablated material. Similarly, there are a number of nonoptical approaches that represent variations of some of these schemes that have

produced success. For example, laser-enhanced ionization uses photon absorption combined with thermal excitation to produce enhanced ionization, which ultimately causes a change in the current flowing between a pair of electrodes inserted within the excitation source such as a flame.

While the general approaches to elemental analysis using optical spectroscopy that have been discussed in the text are currently dominant in analytical laboratories, the wealth of options of producing atoms/ions and detecting their presence in order to identify the elemental composition of a sample keeps the field vibrant and foretells the likelihood of new, improved methodologies. The ultimate objective of analytical developments in this area is to devise a means of conducting elemental analysis faster, cheaper, and

more accurately on a wider variety of sample types. Improved precision, sensitivity, and elemental coverage round out the objectives sought for the ideal instrument.

### What Constitutes a Bioassay?

As Gaddum in 1953 has pointed out, the term bioassay 'may be applied to any experiment in which the potency of a drug is measured by effect on living organisms or tissues'. (In this definition, 'hormone' can be inserted in place of 'drug'.) Gaddum's review of the various types of bioassay and of the mathematical evaluation of such bioassays is still cardinal to this type of investigation. The two more recent fundamental reviews on the mathematical handling of such assays are those of Emmens, 1969 and that found in the European Pharmacopoeia, 1971.

Before progressing further, it is essential to define the term 'bioassay'. In agreement with Gaddum, the term covers those assays that involve either whole animals or isolated tissues and is extended to include assays done on isolated cells. Assays performed on fragments of cells, such as isolated membranes or other cell fragments, are not included, since these

deal with the immediate binding of the hormone, not the intracellular effect of the hormone. Assays performed on isolated cell receptors are also excluded: the same receptor will bind specific inhibitors of the hormone and it will be difficult to differentiate this binding from that of the hormone. The essence of a bioassay is as follows: the hormone (or drug) binds to its specific site, or receptor; when sufficient concentration of the hormone is bound, it stimulates a response. The immediate response might be an activation of some 'second messenger' system, such as the formation of cyclic adenosine monophosphate (cAMP). But this 'messenger' is produced by many stimuli: it is not specific to this hormone, whereas the final intracellular response is indeed specific to the hormone. Therefore, a true bioassay must involve at least whole cells, preferably in intact tissue, responding to a specific intracellular response.

### Validation of Bioassays

A bioassay involves measuring how well a preparation of the hormone, or a sample of plasma, activates a biological function in its target tissue; this is compared with how well graded concentrations of a standard preparation of that hormone perform that function.

For example, intravenous injection of graded concentrations of the adrenocorticotrophic hormone (ACTH) into hypophysectomized rats caused a graded loss of ascorbate from the adrenal glands.

Improvements to this technique, with the retrograde injection of the test, and standard, material into the adrenal gland improved the sensitivity of this assay to  $100 \text{ pg ml}^{-1}$ , which was just sufficiently sensitive to detect pathologically elevated circulating levels of this hormone. Modification of the procedure used on isolated cells improved the detection level to  $1 \text{ pg ml}^{-1}$ .

The cytochemical bioassay (discussed later) involves six segments of the adrenal glands of a guinea pig. Four segments are used to produce a calibration graph of the effect of logarithmically graded concentrations of a standard preparation of the hormone and the other two are exposed to different concentrations of the plasma (or other type of sample) to be tested; the dilutions of the plasma are normally 1:100 and 1:1000. The limit of detection by this bioassay is  $0.005 \text{ pg ml}^{-1}$ . A typical cytochemical bioassay of ACTH in a sample of human plasma is shown in Figure 1.

### Statistics and Probability

The basic criterion of a bioassay is the index of precision ( $\lambda$ ). This depends on the slope of the logarithmic dose-response graph ( $b$ ) and the standard deviation ( $s$ ) of the points from the line (obtained by subtracting each value of  $y$  from its recorded value  $y_c$ ):

$$s = \frac{\sum (y - y_c)^2}{n - 1} \quad [1]$$

where  $n$  is the number of readings. From this value one can calculate  $\lambda = s/b$ . (It may be noted that, in some publications, the term  $s_{yx}$  is used instead of  $s$ ).

**Figure 1** Result of a typical cytochemical bioassay, the assay of ACTH in human plasma. Four segments of the adrenal glands of one guinea pig are exposed to graded concentrations (crosses) of a standard preparation of the hormone in T8 medium. Two segments are exposed to one of two concentrations of the plasma in T8 medium (broken lines); when corrected for dilution, the values are consistent.

Generally, when  $\lambda = 0.3$ , the log dose estimated from a single observation has a standard error of 0.3. Consequently, within the limits of a single standard deviation (SD: 68% confidence limits) this single observation would be in error to plus/minus the antilog of 0.3, namely two times or one-half the value (50% to 200%) produced by the assay. Surprisingly, this is often considered the upper limit of an adequate assay. However, most bioassayists would aim towards a value of  $\lambda$  of 0.1, which implies that a single observation would have a 68% probability (i.e. one standard deviation) of being from 79% to 126% of the correct value. If one wants more precision, namely two standard deviations (95% confidence limits), a  $\lambda$  of 0.1 would give 63% to 158% of the true value.

A more exact indicator of the precision of a bioassay is given by the fiducial limits. To calculate these generally requires at least two dilutions of the test material and two or three of the standard reference compounds (as in Figure 1). These calculations take into account the degree of parallelism of the response of the test as against that of the standard (also see below). The equations for calculating these are given by Gaddum (1953) and by the European Pharmacopoeia (1971).

### Other Factors Involved in Assessing Bioassays

**Accuracy** In terms of bioassay, the accuracy of an assay is given by the percentage recovery of the pure substance that was added to the sample before the assay was done. In normal practice the hormonal content of an aliquot of a sample of plasma is first determined. Then a known amount of a standard preparation of the hormone (e.g.  $100 \text{ mU ml}^{-1}$ ) is added to the sample and a second aliquot is assayed. If, for example, the first sample was assayed at  $10 \text{ mU ml}^{-1}$  and the second at  $105 \text{ mU ml}^{-1}$ , the percentage recovery was 95%.

**Sensitivity** Sensitivity is defined by the smallest change in concentration of the hormone, or its lowest concentration, that can be measured significantly different from 'background' by the assay system.

**Variability** Variability essentially tells you how much reliance can be placed on the bioassay system. Ideally a single sample should be assayed on a number of occasions: to what extent do the results vary? It should also be remembered that some specimens may deteriorate with time of storage: this is also useful information.

**Specificity and Parallelism** The results given by two or three different concentrations of the test material

are plotted against those obtained from similar concentrations of the standard preparation (as in **Figure 1**). Generally, whether the responses are parallel can be determined by simple inspection. For greater precision mathematical methods can be used. It is only when the graphs are parallel that it can be assumed that the test material is likely to be the same as that in the standard preparation. This is a much more rigorous criterion than is used in immunoassays.

## Do We Need Bioassays?

All biologically active molecules are characterized by their biological activity as measured by a 'functional assay'. In contrast, there has been a tendency to rely on 'analytical assays', including saturation assays and physicochemical analytical procedures such as high-pressure liquid chromatography. The argument is that since hormones are specific chemical moieties, they should be analyzed by the highly sophisticated analytical procedures that have been developed recently. These usually are rapid and automated, and many can be done by relatively unskilled operators, whereas bioassays are more cumbersome and much more time-consuming.

The surprising fact is that bioassays are chemically more discriminating than are the new analytical procedures. This arises from the fact that quite minor changes in the hormone molecule can produce major physiological effects. For example, the terminal 1–34 part of the parathyroid hormone molecule (1–34 PTH) is fully active on bone and on kidney but desamino 1–34 PTH has only 1% of this activity in the renal adenylcyclase assay and 50% of the 1–34 PTH activity in the *in vivo* bone hypercalcemia assay. Further modification of the PTH molecule (3–34 PTH) removes all biological activity. It might be argued that such a change in the molecule would be detected by analytical methods. However even slight alteration in what is normally regarded as the 'biologically inert' region of the PTH molecule, changing aspartate in place of asparagine at position 76, can cause almost complete loss of PTH-like activity.

This highlights a worry about the current widespread use of immunoassays in that such assays do not monitor each part of the whole molecule. Even with immunoassays that have antibodies directed to several regions of the hormone, it is likely that a very small change, such as the asparagine residue to an aspartate residue, would not be noted, yet the striking loss of biological activity that this has been shown to entail would certainly be noted by bioassay. In fact there was a fairly recent, widespread example of this type. There was a great deal of

concern about a bone peptide, osteocalcin, and whether it had a role in ossification. The evidence, from radioimmunoassay of circulating levels of this peptide, was entirely contradictory. However, it was then realized that the important role of this peptide depended on the carboxylation of three glutamate residues to  $\gamma$ -glutamate (Gla): it was this carboxy-glutamate that was involved in binding calcium, not the normal glutamate residues, but the radioimmunoassays at that time were incapable of distinguishing between the biologically inactive and the biologically active (Gla-form) of osteocalcin.

There are still several entities that have considerable biological activity but for which no immunoassay is available. The most commonly found example of this is the long-acting thyroid-stimulating immunoglobulin of Graves disease, which can be assayed by the same cytochemical bioassay as is used for measuring circulating levels of thyroid-stimulating hormone except that the response is very much delayed. Equally, the levels of thyroid growth-stimulating immunoglobulins, associated with goiter, and the immunoglobulins that are related to the blockade of thyroid function in myxoedema have to be measured by suitable bioassay. Other examples include the assay of the anti-parietal cell immunoglobulins of pernicious anemia and some, as yet uncharacterized, natriuretic factors.

## Function of Bioassays

### Testing the Functional Potency of Hormone Preparations

The World Health Organization (WHO) Expert Committee on Biological Standardization is responsible for establishing international standard and reference preparations of hormones. The activity of other preparations of the hormone, or of the hormone in the circulation, is referred to this standard. That committee recognized that 'a limitation on the use of immunoassays for evaluating hormonal bioactivity is that the methods measure a composite of antigenic activity, which is not necessarily related to the bioactivity of the hormone'. Several excellent preparations of hormones have been obtained by the WHO only for it to be found that, while they gave high values by immunoassay, they had little effect in bioassays. Such preparations become labeled 'for immunoassay only'. This problem became more severe when polypeptide hormones began to be prepared from human tissue. There was too little of the final, purified hormone for it to be assayed by conventional bioassay and the WHO Expert Committee called for the development of new, very micro

bioassays to cope with this problem. That was the basis of the development of the cytochemical bioassays (discussed later), which required only 10 pg for each assay.

### **Discrepancy between Clinical Assessment and Immunoassay**

If a clinician suspects a hormonal disorder, the circulating level of that hormone in the patient needs to be measured. This can be done either by a functional procedure (i.e. bioassay) or by an analytical method such as immunoassay. Since a hormone is defined and recognized by its biological function it would be reasonable to measure its presence by bioassay, which depends on its function. This is measured in terms of units of activity relative to that of a standard preparation of that hormone. On the other hand, bioassays are laborious and time-consuming relative to immunoassays, which measure how much of that hormone molecule is present. In general, bioassays and immunoassays have produced similar results, so that it is obviously expedient to use the latter. However, there are many instances in which the two results have proved very discrepant. There are examples where immunoassay has given misleadingly high results: in some instances it has included in its measurements molecules such as 'big gastrin' or 'big ACTH', which are relatively inactive biologically; in others, immunoassay measured biologically inactive fragments of the hormone, especially where these have a long half-life in the circulation, as occurred with assays of parathyroid hormone in secondary hyperparathyroidism.

An unusual example concerns the presence of a PTH-like factor in the circulation of cancer patients. The clinical condition indicated a considerable concentration of PTH-like activity, associated with loss of bone and hypercalcemia (the hypercalcemia of malignancy). Immunoassay detected no elevated PTH levels; only the cytochemical bioassay was able to show high concentrations of PTH-like activity, although such activity did not show true parallelism. The material causing this effect has now been isolated and purified: it is known as the PTH-related peptide.

### **The Study of Hormonal Effects**

Often the name of a hormone is related to the first effect that the hormone has been shown to influence. For example, although prolactin may indeed have effects on the lactating breast, it has far-reaching influences other than this. Consequently, it is often valuable to study the cellular mechanisms influenced by a hormone other than that activity by which it is

generally named. This type of investigation necessarily depends on some form of bioassay; the cytochemical bioassay system is particularly useful because of the range of activities that can be monitored by it. A particular use of these methods has been the analysis of the peculiarities involved in the condition known as pseudohypoparathyroidism type I. (It may also be related to nutritional vitamin D deficiency). In this the often huge discrepancy between immunoassayable PTH-like material and very low biologically assayable PTH has been shown to be due to material that is detected by immunoassay but which, in fact, inhibits true PTH activity. The inhibiting material has now been isolated.

### **The Information That can be Obtained by Bioassay**

Some critics of bioassays have been concerned that the bioactivity of a hormone may vary depending on how the hormone is administered to the whole animal, for example intravenously, intraperitoneally, or intramuscularly. Another criticism is that *in vitro* bioassays do not always distinguish between sialated and desialated forms of the hormone. In the authors' view, these criticisms show a fundamental ignorance of the purpose of bioassays. Thus, a bioassay should measure the concentration of the hormone that, acting on the relatively intact target tissue (or cells), produces a measured response. In practice, this is related to the response produced by a standard preparation of that hormone acting under identical conditions. The fact that a hormonal preparation becomes modified in the circulation should be immaterial to the bioassay of that hormone: that is a question for a physiological study.

### **Whole-Organism Bioassays**

The most widely used whole-animal bioassay consists of variants of the original McKenzie assay for the thyroid-stimulating hormone (TSH), which provides a type-example of bioassays in intact animals.

The general procedure is as follows. Female mice, of about 15 g, are fed a low-iodine diet for a week. They are then injected intraperitoneally with 5–8  $\mu\text{Ci}$  of radioactive iodine ( $^{131}\text{I}$ ). Thyroxine (10–15  $\mu\text{g}$ ) is injected 4, 24, and 48 h after this injection. Twenty-four hours after the last injection of thyroxine, the samples to be analyzed, namely concentrations of the unknown and of a standard preparation of TSH, are injected into the tail vein of the mice. (In some modifications, thyroxine is added to the feed, or to the drinking water). At the time the TSH was injected,

and 2 h later, blood samples are taken for determining the radioactivity present. The percentage increase in radioactivity, with increasing concentrations of the preparations, is plotted on a log-dose scale. It should be linear over a useful range. The method detects 0.25 mU of TSH activity (reported to range from 0.17 to 0.29). However, as with most 'whole-organism' bioassays, the method is not sufficiently sensitive to measure plasma levels within the normal range.

By determining the radioactivity in blood samples 9–24 h after the material to be assayed has been injected, it is also possible to assay the long-acting thyroid-stimulating immunoglobulin (LATS).

Both  $2 \times 2$  and  $2 \times 3$  assay designs have been used, with 6–12 mice for each dosage point.

Other *in vivo* bioassays, including those for the follicle-stimulating hormone (FSH), for the luteinizing hormone (LH) and for the growth-stimulating hormone (GH), have been described but are not used much nowadays.

## Isolated-Cell Bioassays

Cells have been isolated from many organs, including the pituitary, adrenal and thyroid glands, the testes and the corpus luteum. They have been used, without being maintained *in vitro*, for assaying the relevant hormones. Possibly the most used of such bioassays are those for LH and the structurally similar human chorionic gonadotrophin. The isolated cell bioassay of LH is used here as an example. This is an unusual isolated cell bioassay because it does assay the plasma directly; in most other assays the isolated cells have become modified so that plasma is cytotoxic to them.

Small pieces of adult mouse testis are placed in Eagle's medium with 2% calf serum (6 testes/50 ml) and stirred for 10 min to liberate the cells. The medium is then filtered to remove pieces of tissue. The filtrate, containing the isolated cells, is preincubated (1 h at 37°C in an atmosphere of 93.5% O<sub>2</sub>–6.5% CO<sub>2</sub>) in a shaker at low speed. The cell dispersion is then placed in ice and centrifuged for 5 min at 4°C at low speed. The supernatant is discarded and the cells are resuspended in Eagle's medium containing 2% calf serum.

Cell suspension (0.1 ml, containing  $6 \times 10^4$  cells) is added to tubes, in ice, that contain 0.1 ml of the appropriate amount of the gonadotrophic hormone in Eagle's medium containing 2% calf serum. The samples (test and controls) are incubated at 34°C for 3 h, at 80 rpm in the O<sub>2</sub>:CO<sub>2</sub> atmosphere. The amount of testosterone produced is measured by

radioimmunoassay; the response is rendered linear by suitable mathematical adjustment.

The method appears to be highly specific, with an index of precision of 0.044 (19 assays). It is also sufficiently sensitive for assaying circulating levels of the hormone. In samples taken over the entire menstrual cycle, the biological activity measured by this assay was consistently ~5.5 times that recorded by immunoassay.

## Isolated-Tissue Bioassays

### Background

The main isolated tissue bioassays are the cytochemical bioassays (CBA). These are  $\sim 10^3$  times more sensitive than the equivalent immunoassays, so that they readily measure normal, and subnormal, circulating levels of the hormones. Because of their sensitivity, very little plasma is required; even a heel-prick from a neonate is sufficient. They are very specific in that they depend first on the specific recognition of the hormone at the surface of the target cells, and then on the provocation of the relevant 'second messenger' to transmit the message to the specific intracellular metabolic system that will give rise to the biochemical mechanism by which that hormone is normally recognized. These bioassays measure the altered metabolic system. The considerable sensitivity of these bioassays arises from a number of factors: (1) they are 'within-animal' assays, so obviating the variability imposed by using several animals for each point; (2) the hormone is not diluted into the large volume of circulating blood, as in whole-animal assays, but is applied directly to the target organ; and (3) the metabolic activity within the target tissue is allowed to recover from such previous stimulation as may have occurred inside the test animal before the hormone (or the plasma) is allowed to act on the target cells.

### Procedure

Small segments (e.g., one-third of a lobe of a thyroid gland for the TSH assay) of the target tissue of a suitable animal (normally a guinea-pig or a rat) are placed on lens tissue on a metal grid table in a vitreosil dish in a culture vessel (**Figure 2**). Trowell's T8 medium is added to the vitreosil dish until it reaches the lens tissue, but does not overflow it. This medium contains amino acids and a balanced mixture of salts and is suited to these nonproliferative organ-maintenance cultures. The culture vessels are gassed with a mixture of 95% O<sub>2</sub>–5% CO<sub>2</sub> and sealed. They are left for 5 h to allow the tissue to recover from the trauma of excision and from the effects of

**Figure 2** The vessel for organ culture. The method is described in the text.

previously circulating hormones. This allows the metabolic activity of the cells to revert to basal level. Then the culture medium is replaced by a fresh sample of T8 containing one of four dilutions (e.g.,  $5 \text{ fg ml}^{-1}$  to  $5 \text{ pg ml}^{-1}$ ) of the standard preparation of the hormone or of one of two dilutions of the plasma, normally at 1:100 and 1:1000 concentrations in T8 medium (as in **Figure 1**). The use of unextracted plasma obviates any degradation of polypeptide hormones that could occur during the separation of the serum and also the possible release of active moieties such as polyamines from the blood cells. The duration of the exposure of the segments to the concentrations of the standards or of plasma to achieve the first, rapid response to the hormone is normally very short: for example 4 min in the ACTH assay or 8 min in the assay of parathyroid hormone. The tissue is then chilled to  $-70^{\circ}\text{C}$  for 1 min and transferred to cold, dry tubes at this temperature for storage, which may be a matter of a day or two.

Sections are cut in a cryostat fitted with an automatic cutting device to ensure sections of constant thickness (to within  $\pm 5\%$ ) with the cabinet temperature at  $-25^{\circ}\text{C}$  and with the knife cooled further with solid carbon dioxide. The sections are flash-dried on to glass slides and reacted by quantitative histochemical methods for the biochemical activity that is typical of the effect of the hormone on its target cells. These methods have been adjusted to ensure no loss of material. The colored reaction

product is then measured, solely in the target cells, by scanning and integrating microdensitometry.

### Section Bioassays

Part of the strength of the cytochemical bioassays is that they are 'within-animal' assays. But normally only six, or at the most eight, segments can be obtained from one animal, four being required for the standard graph and the rest for the two dilutions of the plasma from one, or at the most two, subjects. To increase the 'throughput' of some of these bioassays, it was found possible to use sections, instead of segments.

In these section bioassays, relatively large segments of the target-organ are maintained for 5 h, as for the segment bioassays. The segments are then chilled to  $-70^{\circ}\text{C}$  and relatively thick sections that enclose whole cells are cut (e.g., at  $20 \mu\text{m}$ ). These sections, under suitable stabilizing conditions, are then exposed to the various concentrations of the standard preparation of the hormone or to one of two concentrations of samples of plasma from a number of subjects. The response now occurs in a matter of tens of seconds rather than of minutes. The cytochemical reactions and measurement, the response and the sensitivity, are the same as for the segment bioassays.

### Trends in Bioassay

Routinely, when hormonal assays are done to support a diagnosis, immunoassays are ideal because they are fast, require relatively little skill, and can be done on a large scale. When the results of such assays are at variance with the clinical picture, bioassay becomes essential. A particular recent example of this concerns a new, highly specific immunoassay of luteinizing hormone (LH). In some individuals this gave zero values even though there were indications that these values should have been high. This was then found to be caused by the presence of a molecular variant of LH that assayed normally by bioassay, so emphasizing the importance of bioassay in exceptional cases and in research. Bioassay becomes important also with respect to immunoglobulins that exert endocrine influence, such as those that affect the thyroid gland. It is also important in detecting inhibitory influences that can readily be detected by bioassay. This is done by first doing a straightforward bioassay on the plasma and then adding two known concentrations of a standard preparation of the hormone. The amount of this added hormone that is 'recovered' in the bioassay will indicate whether there is inhibitory material in the plasma.

It may well be that this detection of such material will be a major use of bioassays.

A particular advantage of bioassay is that it can assay material, such as the various thyroid-stimulating or inhibitory immunoglobulins that have eluded other forms of assay. The cytochemical bioassays have practical benefit in that the same expertise and equipment can be used for assaying biologically active moieties, whether they be polypeptide hormones or endocrinologically significant immunoglobulins or factors that inhibit endocrine function.

## Microbial Tests

**N Christofi**, Napier University, Edinburgh, UK

## Introduction

Bioassays are methods that utilize living materials to detect substances and/or determine the potential toxicity of chemicals or contaminated matrices. They are widely used to screen for potential hazardous chemicals in contaminated soils, potable and wastewater, foods, and other materials. Bioassays are important in toxicology, which is the 'study of toxic substances and their effect on organisms and the environment', and are used in assessing acute and chronic toxicity. The general purpose of toxicity testing is to obtain information for use in the management of the release of toxic substances into the environment. Whether a substance is toxic or not depends largely on two factors: the test system being used and the concentration of the chemical. This implies that most substances are potentially toxic if

they are present in the environment at sufficiently high concentrations and it is known that many essential micronutrients are also toxic at high doses. A large number of toxicity bioassays have been used in ecotoxicology. These include rapid screening tests involving microorganisms to multispecies testing utilizing microcosms and mesocosms embracing bacteria, algae, invertebrates, and vertebrates. This article deals with microbiological toxicity tests.

## Analyses of Toxicants

Toxic compounds in natural samples can be detected either through chemical analyses or through bioassay. A disadvantage of the first detection method is that it requires sophisticated instrumentation to determine contaminants in a sensitive and accurate way although often in complex effluents, for example, contaminants are not known and it is therefore not easy to carry out adequate analysis. Some bioassays provide quantitative information on polluting substances but most determine the toxicity of a given

**Table 1** Microbial bioassay methods

Method	Technique
Growth rate, biomass, numbers	Turbidometric, potentiometric, spectrophotometric, biochemical testing, electronic cell counters (e.g., flow cytometer), viable cell counting (MPN), direct observation
Respiration	Respirometric (manometric, electrolytic, DO)
Nitrification inhibition	NH <sub>4</sub> <sup>+</sup> utilization, NO <sub>3</sub> <sup>+</sup> production, Minntox, Amtox
Enzyme assays	Esterases, dehydrogenases, phosphatases
<i>Vibrio fischeri</i> bioluminescence	Biotox, Lumistox, Microtox
Chemiluminescence	Horseradish peroxidase, Eclox, Aquanox
Genetically modified bacteria	Reporter genes, e.g., <i>lux</i> , <i>luc</i> , <i>gfp</i> marked microorganisms
Biosensors for cytotoxicity, genotoxicity	<i>Escherichia coli</i> , <i>Pseudomonas putida</i> , <i>Salmonella typhimurium</i>

sample. A major advantage of a bioassay over chemical analysis is that the former monitors bioavailability.

Toxicity testing involves recording the response of biological material (whole organisms, enzymes, etc.) to a toxicant over a range of concentrations. The concentration, which affects a predetermined percentage of the biological material over a certain time period for a given response, is then calculated. Acute and chronic toxicity assays exist for organism testing. The endpoint of acute toxicity tests has traditionally been death of an organism, which provides information in terms of a lethal concentration (LC). The concentration at which 50% of the test organisms are killed (LC<sub>50</sub>) is the standard assessment in acute toxicity testing. Chronic toxicity testing involves monitoring sublethal effects such as growth, reproduction, or any other activity that will affect the long-term survival of the organism. Results are given in terms of an effective concentration (EC) or inhibitory concentration (IC), depending on the parameter tested.

The use of the term EC and IC should be clarified. Environment Canada advocated that 'inhibitory concentration should be used for any toxicological test that measures a change in the rate in a continuous response. The term effective concentration should be limited to other toxicity tests in which quantal measurements are taken'. Quantal in this context means that at a given exposure concentration a certain percentage of the test organism will show an effect whilst the remaining percentage will not show the effect.

It is impossible to test the toxicity of a chemical to every species and normally the species chosen for testing should be the most sensitive to the chemical in question or environmentally the most relevant. There has recently been a move toward the use of a battery of tests consisting of species from each trophic level in a community, instead of just a single surrogate species, for environmental risk assessment. Traditionally, fish have been the bioassay of choice;

however, the *Daphnia magna* test has also become a standard.

An ideal bioassay should be reliable and reproducible; economic; able to yield statistically robust data; relevant; practicable; readily understood by the layman; able to utilize test organisms continually from reliable stock; simple to emulate; regularly intercalibrated; have a clearly defined endpoint, and sensitive to a wide range of pollutants.

In addition to these qualities the species physiology and ecology of the organisms used should also be well documented.

The problem with most of the traditional tests is that they are long, expensive, and require time-consuming propagation of test organisms from higher trophic levels. The logistics of screening hundreds of chemicals and effluents is therefore not feasible, and there are ethical concerns associated with many traditional tests. Microorganisms and microbial constituents can be cost-effective alternatives to higher organism testing and a number of rapid methods utilizing these have been proposed (Table 1). Most of these tests could be used when microbial parameters are under investigation, and enable screening of large numbers of samples as a preliminary indication of toxicity.

## Bioassays

### Bioassays Using Changes in Growth Rate, Biomass, Numbers

Bioassays utilizing changes in growth rate have been employed to test the effect of chemicals on microorganisms. Such tests tend to be lengthy and labor intensive as they involve the use of techniques monitoring changes in microbial populations and biomass indicators that are not easy to automate. Microorganisms used in tests are either present as single, axenic, cultures or as mixed populations, and are subjected to varying concentrations of toxicants. Techniques used to monitor growth rates or biomass,

including changes in cell numbers, are biochemical analyses, turbidometry, spectrophotometry, potentiometry, electronic counting using, e.g., flow cytometry, viable and total cell counting using cultivation (plate counting or the most probable number (MPN)) or microscopic techniques. With microscopic methodology, dyes are used which can stain all cells, dead or alive, or which specifically target dead or living cells. Staining techniques utilize visible and ultraviolet light for detection. For the latter, fluorescent dyes such as DAPI (4',6-diamidino-2-phenylindole), CTC (5-cyano-2,3-ditolyl tetrazolium chloride), INT (2-(*p*-iodophenyl)-3-(*p*-nitrophenyl)-5-phenyltetrazolium chloride), FITC (fluorescein isothiocyanate), SYTOX Green, LIVE/DEAD. BacLight Bacterial Viability Kit (Molecular Probes) and others can be used. In addition, changes in specific microorganisms can be followed using fluorescent antibodies. Data on temporal changes in biomass are used to calculate, e.g., LC<sub>50</sub> concentrations for specific toxicants.

Toxicity bioassays are available which rely on measuring ATP changes. ATP, a high-energy compound present in all living organisms, is rapidly destroyed when cells die. An ATP luminescence bioassay determines the changes in ATP content of a given inoculum in the presence of toxic substances. Such a method of ATP detection is based on the light producing properties of the luciferase enzyme derived from the firefly. Light is emitted during the reaction of the luciferase enzyme, luciferin (substrate), magnesium ions, and ATP.

The overall reaction may be summarized as

The total light output is directly proportional to the amount of ATP present in the sample.

There are a number of techniques available to extract ATP from cells. Some use trichloroacetic acid (TCA), which also aids in stabilizing the molecule. TCA has a good extraction capacity, is relatively quick, has a reduced potential for human error, and does not discriminate between the different microbiological fractions of activated sludge. Luminescence produced in the luciferin–luciferase reaction can be measured using scintillation counting equipment or a range of luminometers currently on the market.

### Respirometry

Respirometry involves the measurement and interpretation of the biological oxygen consumption. Oxygen consumption is directly associated with both microbial growth and substrate removal.

A heterogeneous microbial community present in a sample allows the system to be flexible, even when challenged with considerable fluctuations of toxicant. Respiration rate is usually measured with respirometers.

All respirometers are based on techniques that measure the rate at which cells take up oxygen. This can be done directly by measuring the rate at which biomass takes up dissolved oxygen (DO) from the liquid or indirectly by measuring gaseous oxygen. Units measuring gaseous oxygen are more sophisticated as they do not need to estimate the oxygen consumption of the samples before the start of an experiment. They include reoxygenation of the culture as oxygen uptake proceeds. Where reoxygenation is achieved by electrolysis, the apparatus is known as an electrolytic respirometer.

Electrolytic respirometers rely on the electrolysis of water to provide the oxygen necessary for the growth of microorganisms in the sample. The inoculated medium is stirred in each respirometric unit, which consists of a closed vessel and an electrolytic cell for oxygen supply. As oxygen is consumed by the biological activity in the reactor vessel a slight vacuum lowers the electrolyte level in the electrolysis cell triggering oxygen production. Oxygen is produced at the positive electrode and added to the reaction vessel until the original pressure is restored. An electrical control unit monitors the amount of oxygen required to equalize the pressure, thus a continuous cumulative oxygen demand readout is obtained and expressed as a concentration. Measurements can be taken for extended periods of time without interruption or reduction of the oxygen content in the reaction vessel.

In ISO 8192, 'Test for inhibition of oxygen consumption by activated sludge', the oxygen uptake of a well-aerated sample of actively respiring sludge is measured using a DO electrode. The decrease in DO concentration is recorded as a function of time. An IC of test substance decreases the oxygen uptake by the microorganisms, and the IC<sub>50</sub> is calculated. The percentage inhibition of the microbial respiration is calculated by comparison with a control mixture without test substances.

Respirometric techniques have been extensively used for the determination of BOD and biokinetic parameters. A recent development is the use of this technique for the respiration inhibition kinetics analysis to quantify the toxic (or inhibitory) effect of xenobiotic compounds on the biogenic-carbon removal in biological wastewater treatment systems.

A number of respirometers are available for bioassay purposes. A common type is the Arthur Respirometer used in toxicity testing and also for

the assessment of treatability of specific sources of wastewater entering a wastewater treatment plant.

### **Nitrification Inhibition**

Nitrification, the conversion of nitrogen from a reduced to a more oxidized state, is carried out by a diverse group of microorganisms including chemoheterotrophic and chemolithotrophic nitrifying bacteria. Nitrogen removal is an important aspect of modern wastewater treatment processes as it prevents eutrophication of inland and coastal waters. Treatment plants employing biological nitrogen removal encounter problems arising from the presence of toxic compounds in the influent to the treatment works. It is therefore important to develop methods for investigating the inhibitory effects of such waters. Methods using pure cultures of nitrifying bacteria or samples of nitrifying activated sludge are adequate for determining the inhibition of nitrification.

There are two principle methods of determining the inhibition of nitrifying bacteria. One of them is based on the changes in the oxygen uptake rate (OUR) of the nitrifying bacteria when an inhibitor has been added. The OUR of the activated sludge is determined initially and then, when a specific inhibitor of the nitrifying bacteria has been added (i.e. allylthiourea (ATU)), the OUR is again determined. The change in activity of the nitrifying bacteria is calculated from the difference in these two rates. As the proportion of nitrifying microorganisms in the activated sludge is quite low, the greatest amount of oxygen consumption is due to the heterotrophic bacteria and a small variation in oxygen measurements may affect oxygen consumption by nitrifiers in nitrogen oxidation. Also, these methods require addition of selective inhibitors and are time consuming. The other type of test is based on the direct measurement of the nitrifying activity by means of the ammonia consumption rate or the total oxidized nitrogen production rate. The measurement of nitrifying activity from the ammonia consumption rate is not as accurate a reflection of activity as the production of total oxidized nitrogen because ammonia can be used in other processes apart from nitrification. Ammonia can be used by heterotrophs as a nitrogen source to yield new biomass and also it can be turned into  $\text{NH}_3$  gas that can be lost from the medium. The measurement of the nitrifying activity by means of the production of total oxidized nitrogen is both a direct method and is a better estimation of the nitrifying activity.

A great deal of work has been published on the OUR of nitrifying bacteria and toxicity methods

have been developed using a biological electrolytic respirometer. As only the total amount of oxygen consumed is measured, ATU is used to distinguish nitrification. Nitrification is evident when the sample without ATU uses more oxygen and at a faster rate than the sample with ATU. Nitrification toxicity tests are performed by inoculating wastewater samples with active nitrifying seed sludge and comparing resulting activities with activities measured for a reference wastewater that is known to support nitrification. The long response time and the laborious procedure make this method unsuitable for toxicity testing.

A proposed mini-nitrification test for toxicity screening is called MINNTOX. The test is carried out in 15 ml capped test tubes placed on a rotating shaker making it easier to screen large numbers of samples. The test is performed using 6 ml of liquid in a 15 ml capped test tube and when the tube is rotated, the liquid is aerated efficiently due to the 9 ml headspace. The gas phase contains a sufficient amount of oxygen ( $\sim 2.5 \text{ mg O}_2$ ) to satisfy the demand for nitrification and sludge respiration during the 2-hour test. A limitation of the test is encountered under extreme conditions with very high chemical oxygen demand concentrations. This method is suitable for volatile compounds; however, the compounds will be distributed between the liquid and gas phases, and therefore the bacteria are exposed to a lower concentration than the nominal concentration added. During the test, equilibrium is quickly attained, and the actual liquid concentration can be easily calculated.

Various modifications of the MINNTOX method have been made to ensure, for example, a nonlimiting oxygen concentration during the performance of the test. The test can be carried out in 30 ml capped test tubes and 10 ml of liquid are aerated during the 2-h test. The method is suitable for the screening of inhibitory wastewaters with high organic loads because it provides a modification with pure oxygen added to the gas phase to ensure nonlimiting oxygen concentrations. In Sweden, this method is now being used for regulatory purposes, including a toxicity limit based on this test.

The method using the production of total oxidized nitrogen to measure inhibition is easy to carry out, makes it possible to screen a large number of samples without any specific equipment, and directly measures nitrification inhibition.

### **Enzyme Bioassays**

Enzymes are known to play a crucial role in the metabolism of all organisms. In living cells they catalyze

**Table 2** Microbial enzyme activities – pathways, enzymes, application, and photometrical and fluorogenic substrates

Metabolic pathway	Enzymes	Photometric substrates	Fluorogenic substrates
Nonspecific hydrolases	Esterases Phosphatases	Fluorescein diacetate Nitrophenylphosphate	Fluorescein diacetate MUF-phosphate
Carbohydrate metabolism	Amylases Cellulases Glucosidases	Amylopectin azure Carboxymethyl-cellulose Nitrophenyl- $\alpha/\beta$ -glucosides	MUF-cellobiopyranoside MUF- $\alpha/\beta$ -glucoside
Protein metabolism	Proteases Alanine-peptidases  Leucine-peptidases	Hide powder azure L-Anilinenitroanilide- hydrochloride Leucine- <i>p</i> -nitroanilide	Casein resorufin L-Alanine-4-Methoxy- $\beta$ -naphthylamide L-Leucine-4-methyl-7- coumarinyl- amidehydrochloride
Electron transport system	Dehydrogenases	Iodonitrotetrazoliumchloride	

the chemical reactions within anabolism, catabolism, or energy transfer. The high specificity of a single enzyme to transform a single substrate to the product is fundamental for analyzing specific substances. Enzyme tests are usually carried out in food analysis and clinical chemistry. The activity of a specific enzyme (substrate turnover per hour) can be used to quantify a substance or to characterize the physiological conditions of organs.

Two approaches to measuring enzymatic activity exist. *In vitro* tests use commercially available isolated enzymes that have been purified and characterized. In medical laboratories *in vitro* enzyme tests are used as diagnostic aids to determine blood constituents. In food chemistry, carbohydrates, organic acids, and alcohols are quantified by using isolated enzymes. The second method is to determine the activity of enzymes *in vivo*. A synthetic substrate labeled with a chromophore is added to the sample. The enzyme in the sample catalyses the cleavage of the substrate chromophore bond and the chromophore can be detected photometrically or fluorometrically. The amount of dye released per hour corresponds to the enzyme activity as substrate turnover per hour.

Organic and inorganic materials of natural or anthropogenic origin are mainly degraded by microorganisms. Degradation of these substances provides a continued source of nutrients and energy. Microorganisms catabolize organic and inorganic extracellular materials using exo-enzymes. These are mostly bound to the cell membrane but some are also released into the surrounding soil or water. Both organic and inorganic materials may be transported through the cell membrane into the lumen of the cell where it is degraded by endoenzymes. The

determination of enzymatic activities *in vivo*, therefore, is an indicator of microbial degradation in soil, sediment, and water. Table 2 shows a list of existing tests to determine enzymatic activity *in vivo*. The methods to determine enzymatic processes in aquatic habitats are well established and one method used to determine alanine aminopeptidase fluorimetrically is now a DIN (Deutsches Institut für Normung) standard. The use of *in vivo* enzymatic tests for toxicity testing has been used and compared to other microbiological testing techniques.

### Bioluminescence/Chemiluminescence

Chemiluminescence is the emission of photons (electromagnetic radiation as light) when chemically excited molecules decay to ground state following a chemical reaction. In bioluminescence, light emission involves reactions in living organisms. The marine luminescent bacterium *Vibrio fischeri* produces light in a luciferin–luciferase system, linked to the energy transfer in the cell and to respiration. This light can be measured in a suitable luminometer. *Vibrio fischeri* uses the fluorescent pigment luciferin as a terminal electron acceptor. It is therefore an index of cellular metabolism. Toxicity is defined as causing a disturbance to the normal metabolism of the bacterium. The degree of toxicity is proportional to the measured light loss.

In the *V. fischeri* bioassay, the reduction in light output from a suspension of the bacteria on exposure to a toxic sample is monitored. A control is used to detect natural light decrease over time. In the acute test, measurements can be made at intervals of usually 5, 15, or 30 min. The result is often given in terms of an EC<sub>50</sub> (EC that results in a 50% reduction

in bacterial light output). Quality controlled *V. fischeri* bacteria are freeze-dried to maintain their physiological state during storage and are reconstituted on use. Various manufacturers produce versions of this test and testing bacteria (including AZUR; BioOrbit; Dr. Lange; Merck). A chronic test has also been devised. The *V. fischeri* organisms have also been immobilized for toxicity testing.

Chemiluminescent-based toxicity bioassays rely on the reaction of luminol with an oxidant to form light that can be monitored using a sensitive luminometer. Horseradish peroxidase, an enzyme that catalyses the reaction between the oxidant and an enhancer, can be used to generate an enhancer radical reacting with luminol to produce a luminol radical emitting light. In this bioassay, chemicals that scavenge free radicals (e.g., antioxidants) and enzyme inhibitors can reduce the light output of the reaction and this is usually dependent on the concentration of the toxicant. A number of proprietary chemiluminescence tests are available on the market (e.g., Eclox, Aquanox).

### **Reporter Genes/Whole Microbial Cell Biosensors**

The use of DNA in diagnostics has increased in recent years and is likely to become more important following the now completed Human Genome Project and the rapid elucidation of more and more microbial genomes. Reporter gene technology and biosensors can make use of DNA in the development of toxicity bioassays that are rapid, sensitive, and cost-effective.

Microorganisms can be genetically modified to harbor genes that generate a 'reporter' signal in response to a specific recognition event. This can be achieved by fusing together two genetic elements. The first element is the promoter that is activated by an analyte or toxic substance, and, this in turn activates the second element, a reporter gene. Reporter genes code for RNA and proteins that are different from the normal intracellular and extracellular molecules of a particular microorganism. They can be used in bioanalytical methods to produce signals indicating the presence of a target analyte. Reporter genes are often used to detect transcriptional activity within cells. Reporter proteins include alkaline phosphatase, beta( $\beta$ )-galactosidase, bacterial luciferase, and various fluorescent proteins such as green fluorescent protein. In addition to not being induced endogenously, the reporter gene should respond to stimulus in a rapid and quantifiable manner. Constitutive promoters are also used in stress responses where toxicity is monitored by a reduction in microbial metabolism affected by chemicals. For example, recombinant bioluminescent bacteria exhibit

light reduction in the presence of toxic or lethal chemicals concentrations.

Bioluminescence genes (*lux*, *luc*, *Aequorin*) are most commonly used in biosensors for monitoring toxicity and measuring pollutants. In response to analytes, including pollutants, microbial pathways involved in metabolism or stress may be activated. This results in the expression of one or more genes. If the expressed gene has a bioluminescent reporter gene fused within its promoter sequence, transcription of the reporter mRNA and protein synthesis will take place, indicating activation of the pathway. In this case there is rapid detection of activation manifesting in light emission by microbial cells measured using a luminometer. The use of reporters, which do not give an optical signal, would require additional assays to detect mRNA, the reporter protein or its enzymatic activity.

Bioassays utilizing reporter gene technology are available for a wide range of substances and genetically modified microbial cells can be used to detect organic and inorganic chemicals in natural samples. Numerous organic constituents in samples can be detected including naphthalene, toluene, phenolics, and inorganic elements such as Hg, As, Cu, and Pb. Assays can be carried out using microorganisms in suspension or immobilized onto surfaces or in specific matrices. Suspension bioassays have used microtiter plates and microplate luminometers such as Anthos Lucy 1, Dynatech, Berthold, where an optical signal is produced.

Generically, a biosensor is a device that incorporates a biological sensing element in close contact with a transducer that can convert a biological change in the sensing element to a measurable physical response. Microbiological sensing components include whole cells, nucleic acids, enzymes or enzyme components, ion channels, receptor molecules, or antibodies. The transduction technique may be potentiometric, amperometric, conductimetric, impedimetric, optical, calorimetric, or acoustic and depends on the signal emitted by the biosensor.

An optical toxicity biosensor device can utilize light-emitting bacteria immobilized directly onto a surface or incorporated in a polymer that is directly deposited onto glass or other surfaces. Toxicants added onto the immobilized bacteria cause an increase or a decrease in light output that is measured by a sensitive photo diode situated below the immobilized bacterial film.

Environmental chemicals, both natural and synthetic, play an important role in the cause of human cancer because they can react with DNA (genotoxic). This led to the development of a reverse mutation test, the Ames test, using auxotrophic bacterial

mutants, such as strains of *Salmonella typhimurium* requiring histidine (*his*) for growth. The test involving *his* mutants of *S. typhimurium* relies on point mutations of one or more DNA base pairs reversing the initial mutation in the test organism enabling it to become prototrophic for the essential amino acid (non-histidine-requiring). Point mutations are often the cause of many genetic diseases in humans. The Ames test is a relatively complex procedure requiring numerous manipulations and more than one day to perform. Genotoxicity can be detected using reporter gene technology where the reporter gene is associated with genes involved in DNA repair (SOS response involving > 30 genes such as *Rec*, *Lex*, *uvrA*, etc.). Thus, in the case of bioluminescence genes, DNA damage will activate the stress promoter which will lead to light emission.

## Bioautography

**L Botz, B Kocsis, and S Nagy**, University of Pécs, Pécs, Hungary

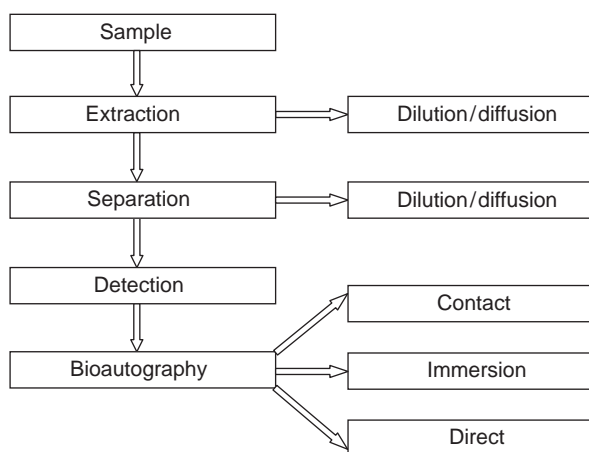

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Bioautography is a postchromatographic detection method that is widely used for the bioassay of antimicrobial effects. This technique is based on paper or thin-layer chromatography (TLC) separations. Bioautography detects the growth-inhibiting or growth-promoting biological effects of the applied substances. Various bioautographic assays may be used to detect antibacterial, antifungal, antiprotozoal, and cytotoxic substances. The bioactivity-based bioautographic analysis is the most effective method to detect antimicrobial compounds because it detects activity even in complex sample material. Paper chromatography or TLC combined with other analytical techniques is the best separation techniques for bioautography. The combined chromatographic and microbiological assays must be carried out under controlled conditions as the experimental circumstances significantly influence the results. The combination of microbial bioassay with extraction and separation methods is summarized in Figure 1.

The potential applications of bioautography are the following:

1. Additional detection methods in the screening of samples.
2. Targeted or bioactivity-driven isolation processes.
3. Detection of antibiotic residues in human or animal food.

**Figure 1** Flowchart illustrating the combination of the microbial bioassay with the separation techniques.

4. Tool to investigate the activity of the products of pharmaceutical preparations, combinatorial chemistry, and microbial extracts.
5. Part of combined methods for standardization of extracts from biologically active materials (e.g., medicinal plant extracts).
6. Special and selective substance-specific postchromatographic detection processes.

## Theory of Detection Assay

The methods for detection of antimicrobial activity may be classified into three groups: (1) dilution, (2) diffusion, and (3) bioautography.

The dilution method mixes the samples with a suitable medium inoculated with the test organism. After incubation the growth of the microorganism can be determined by direct visual or turbidimetric comparison between the test culture and the control culture. The diffusion method is an agar-overlay method that uses disk, cylinder, or hole as a reservoir for the microorganism to be tested. In the disk method, a filter-paper disk treated with the sample substance is placed on the surface of the agar block inoculated with the microorganism. In the hole-plate method, the samples are placed in a vertical hole in the solidified agar layer. The sample diffuses into the agar where it inhibits or stimulates the growth of the microorganisms around the hole (Figure 2). The cylinder method is similar to the hole-plate method. The sterile cylinders containing the sample are usually placed on the agar surface. After incubation the cylinders are removed and the average diameter of each zone of growth is measured.

There is no relationship between the diffusive power and the antimicrobial activity. The diffusion method cannot be employed when the sample contains lipophilic compounds or with complex samples prepared without separation.

The well-known AMES test is a similar technique in principle. This widely used, simple, and rapid bacterial mutagenicity test detects carcinogenic effects of chemicals. It is based on two assumptions. First, cancer is commonly caused by damage to the cell DNA resulting in somatic mutations. Second, chemicals that damage bacterial DNA and induce mutations are also likely to induce mutations in mammalian cells.

The bacteria-reversed mutation test is another method to investigate the mutagenic and teratogenic effect of chemicals. This uses numerous amino acid-dependent strains of *Salmonella enterica* (formerly *S. typhimurium*). The histidine-dependent strain of *S. enterica* has artificially induced point mutations. The test is carried out in a histidine-deficient bacterial medium. The histidine-independent bacterial

**Figure 2** Types of the migration of separated substances from the chromatoplates to the culture medium. (A) Filter paper disk, (B) cylinder, (C) hole plate, (D) contact or agar-diffusion, (E) immersion or agar-overlay, (F) direct, and (G) upper view of the developed and detected sorbent layer. The white spots show the inhibition zones (F: eluent front).

colonies may arise from spontaneous reversions. When a chemical, or a potential mutagen, is added to the plate, the number of revertant colonies per plate increases in proportion with the applied dosage. The mutagenicity of a substance is determined by comparing the control with the treated culture.

In bioautography, the compounds are separated by chromatography and extracted from the sorbent, then diffused into the inoculated agar. There are three variations of bioautography: (1) contact bioautography, where the antimicrobial compounds are transferred from TLC plate to the inoculated agar plate by direct contact, (2) immersion or agar-overlay method, where the developed chromatoplate is covered with the inoculated agar medium, and (3) direct

bioautography, where the microorganisms can be grown directly on the chromatoplate.

The dilution and diffusion methods mentioned above are all well-known classical microbial assays. Only the bioautographic methods are suitable for direct combination of the detection techniques with any kind of chromatographic separation methods. This technique opens up new avenues to detect the effects of samples on microbes after separation of the compounds by opened sorbent-bed (e.g., TLC) chromatography.

First, it is essential to ensure the appropriate transport (diffusion) of the compounds from the sample layer to the appropriate medium where the microbes can grow, or to create the suitable conditions for the microbial growth directly on the sorbent material. Second, the selection of microbes suitable for detecting the inhibitory effects of the sample substance is also a crucial step.

## Microbe Selection

The selection of the appropriate test organism depends on the purpose of the assay. In a general-purpose test the selected microorganisms must be as diverse as possible. They must represent all important groups of bacteria with group-characteristic physical and chemical compositions and resistance patterns. It is important to take into account that many crude extracts from medicinal plants have specific inhibitory activity against *Staphylococcus aureus*. This is the result of the synergistic effects of various plant constituents. The conditions required for bacterial growth also affect the bacteria selected. It is general practice that pathogenic and apathogenic aerobic microbes, which can be easily cultivated and sensitive to antimicrobial substances, are chosen. These are the Gram-positive *Bacillus subtilis*, *Bacillus cereus*, *Corynebacterium xerosis*, *Micrococcus luteus*, *Staphylococcus aureus*, *Sarcina lutea*, *Streptococcus aureus*, *Clostridium perfringens*, and the Gram-negative *Escherichia coli*, *Erwinia carotovora*, *Erwinia atroseptica*, *Erwinia herbicola*, *Pseudomonas aeruginosa*, *Pseudomonas syringae* bacteria. From amongst fungi *Cladosporium cucumerinum*, *Candida albicans*, *Fusarium* species, *Penicillium expansum*, *Saccharomyces cerevisiae* are usually chosen.

Sterilization is expensive, time consuming, and requires suitable microbial laboratory conditions. Sometimes it is sufficient to protect samples from contaminating bacteria by using ethanol as an extraction solvent. The TLC plates should be sterile, but generally this is not essential, because the large population of test bacteria will overgrow the few contaminant species. Irradiation of the chromatographic

plate with ultraviolet light is an acceptable method to reduce contamination.

## Cultivation of Test Bacteria

Most bacteria and yeasts can be cultivated on standard Müller–Hinton broth. This broth is a general-purpose liquid medium for the cultivation of large amount of bacteria and may be used to test the antimicrobial susceptibility. Standard test microbes should be obtained from the American Type Culture Collection (ATCC) or from other recognized culture collections, otherwise results cannot be comparable. Sometimes it is necessary to use clinical isolates, when multiresistant microorganisms are selected for the screening studies. Anaerobe bacteria, because of the exposure to oxygen, and slowly growing microbes (e.g., *Mycobacterium tuberculosis*) are difficult or impossible to test by bioautography.

The standard procedure describes the growth conditions to be applied for the strain, age, and growth of the tested organism. When microbes are used the inoculum must be taken from cultures in the exponential logarithmic growth phase. This is the time when multiplication occurs and the culture is the most homogeneous. To evaluate the assay the inhibition effect has to be visualized, and the live, dead, or impeded microbes have to be distinguished.

## Visualization of Inhibition of Separated Compounds

The zones or spots of separated compounds are generally visualized by detecting dehydrogenase activity with tetrazolium salt-based reagents. The metabolically active bacteria convert the tetrazolium salt into red formazan dye (2,3,5-triphenyl-2H-tetrazolium chloride, tetrazolium red). A number of tetrazolium salts were evaluated as potential substrates for the enzymatic reaction, but *p*-iodonitrotetrazolium violet, tetranitro blue tetrazolium, and MTT were found to be suitable substrates. The equations below show the principle of the reaction with tetrazolium salt, 3-[4,5-dimethylthiazol-2-yl]-2,5 diphenyltetrazolium bromide (MTT, tetrazolium dye).

NADH/NAD<sup>+</sup> = nicotinamide adenine dinucleotide, pyruvate = pyruvic acid, formazan = tetrazolium dye, LDH = lactate dehydrogenase.

The MTT is reduced to formazan by the NADH, which is generated in the NAD-dependent lactate dehydrogenase reaction. The presence of detergents such as Triton X-100 surfactant (alkylaryl polyether alcohol) accelerates the reduction of the tetrazolium salt manifold. After an additional incubation inhibition zones become visible. The antibacterial compounds appear as clear spots on the colored formazan background.

The obligate aerobic bacterium like *Xanthomonas pruni* does not reduce tetrazolium dyes. The visualization can still be carried out by modification of the assay. The developed plate is pressed onto the agar plate that contains phytopathogenic microbes. These microbes hydrolyze the incorporated gelatin and starch in the nutrient agar, and produces acid from several sugars. The result can be detected by incorporation of bromocresol purple into the media. After transferring the chromatograms onto the agar medium the visualization of the separated cytotoxic antibiotics can be carried out with 2,6-dichlorophenolindophenol (Tillman's reagent, phenolindo-2,6-dichlorophenol). The viable test cells reduce the dye while the dead cells do not.

## **Contact or Agar Diffusion Bioautography**

The typical bioautography method is based on the migration of the antibacterial compound from the chromatographic plate to the inoculated agar plate by diffusion. The chromatographic plates are placed on the surface of agar plates inoculated with microorganisms. After 15–30 min the chromatographic plates are removed and the substances that already diffused into the agar inhibit the growth of the test microbes. Inhibition zones can be easily visualized by the use of suitable microbe strains and mainly dehydrogenase-activity-detecting reagents. The advantage of this technique is that before the antimicrobial test the heterogeneous samples are separated by TLC. The antibacterially active spots can be located. Agar-diffusion assays are particularly applicable to polar and moderately polar compounds. It could be further improved for antitumor antibiotics by applying an appropriate filter paper placed between the inoculated agar and the plate.

## **Immersion or Agar-Overlay Bioautography**

In agar-overlay or immersion bioautography, the developed plate is covered with agar medium. After solidification the plates are inoculated with the

microorganism and growth or inhibition bands can be visualized. Active compounds are transferred from the stationary phase to the agar layer by diffusion. Agar medium is essential in bioautography and provides optimum conditions for bacterial growth. The use of agar gel as a support medium has, however, considerable disadvantages including slow diffusion and bad contrast. In order to achieve longer incubation time, potassium nitrate is incorporated into the basal and seeded agar layers to overcome the problem of limited oxygen availability. After incubation, the plate is sprayed with a tetrazolium salt (e.g., MTT), which is converted to a formazan dye by the microorganism. This technique is a hybrid of the contact and direct bioautographies.

Generally, a less stringent mobile phase (appropriately altered solvent composition of the eluent) is recommended during chromatography in order to achieve increased sensitivity and selectivity of the microorganism in the agar plate or nutrient broth.

It must be noted that there are no sharp division lines between the different techniques. By the use of bioautographic methods great variety of assays can be carried out.

Preliminary screening of anthracycline antitumor antibiotics and the antifungal activity of polyphenols have been tested by the use of bioassay-driven fractionation. Sometimes the reduction of the thickness of the agar layer is beneficial. This is often the case when antifungal compounds are probed and activity-driven fractionated with indicator microorganism *C. albicans*. The essence of this modification is that the inoculated medium is poured rapidly onto the developed chromatogram. The agar overlay method requires the transfer of the active compounds from the stationary phase into the agar layer by diffusion. The thin agar films facilitate this process.

## **Direct Bioautography**

In direct bioautography, the microorganism cultures grow directly on the TLC plate. Each step of the method is performed on the plate. Originally, this method was developed for spore-producing fungi like *Aspergillus*, *Penicillium* and for bacteria. The suspension of the microbial liquid culture is poured over the developed TLC plate. Incubation in a humid atmosphere enables growth of bacteria, and dehydrogenases from the living microorganisms convert tetrazolium salt into the corresponding red formazan. The locations of antibacterial activity can be easily visualized as the antibacterial compounds appear as clear spots on the red background. The sensitivity of the assay enables determination of the minimum active concentration or the minimum

amount of compound. The quantitative determination of compounds by bioautographic analysis can be also implemented by regression analysis of the sizes of the zones or bands. In a simple procedure, *Glomerella cingulata* is directly sprayed onto TLC plates and fungitoxic compounds detected. The detection of inhibitors of *Erwinia carotovora* and *E. herbicola* on TLC plates is also possible. In this case suspensions of the bacteria are sprayed onto the TLC plates by the use of a fine spray. Even the phototoxic furocoumarin compounds can be determined by using the fungus *Penicillium expansum* as the test organism, spraying the TLC plate with a suspension of conidia and irradiated with UV light. With the modification of this technique it is possible to detect the pollen germination inhibitors on TLC plates.

A ready-to-use kit (Merck, Germany), called Chrom Biodip Antibiotika, has recently become available. This was developed for special direct bioautographic detection. This kit contains a premixed culture medium, *Bacillus subtilis* spore suspension, nutrient medium, and MTT detection reagent. Generally, these methods require only heater and therefore it is possible to use this detection in a conventional chemical laboratory. The total determination time is ~21 h. The main advantages of this test kit are: (1) the test needs little laboratory time and cost, (2) the user does not need to maintain strains of bacteria for the test, and (3) the spore suspension can be used at any time.

Overpressured-layer chromatography, also called forced-flow planar chromatography, is an instrumental version of planar liquid chromatography. It develops TLC under controlled conditions. The advantages of this technique are the optimized flow of the mobile phase, the short separation time, the high resolution, the good reproducibility, the high sample throughput, the simple precleaning process, and, finally, the reduced spot or band broadening.

In direct bioautography there is usually no need for diffusion from the adsorbent to the agar medium. Both water-soluble and lipid-soluble substances are in direct contact with the bacteria and the growth medium on the surface of the adsorbent particles. There is no dilution and diffusive loss of the separated substances, and this results in low detection limits.

However, the planar chromatographic adsorbent material is, not always suitable for microbial studies. If the test bacterium requires special conditions (e.g., extremely long incubation time) the advantages of the method may not be exploited. The main factors influencing the evaluation of direct bioautography will be discussed below.

The direct bioautography process can be divided into three steps: (1) growing test bacteria cultures for

dipping, (2) separation of substances for assay by TLC, and (3) microbial assay on the TLC plate. A flowchart for the direct bioautography process is shown in Figure 3.

## Factors Influencing the Microbial Assay

The bioautography screening tests are influenced by many chromatographic and microbial factors.

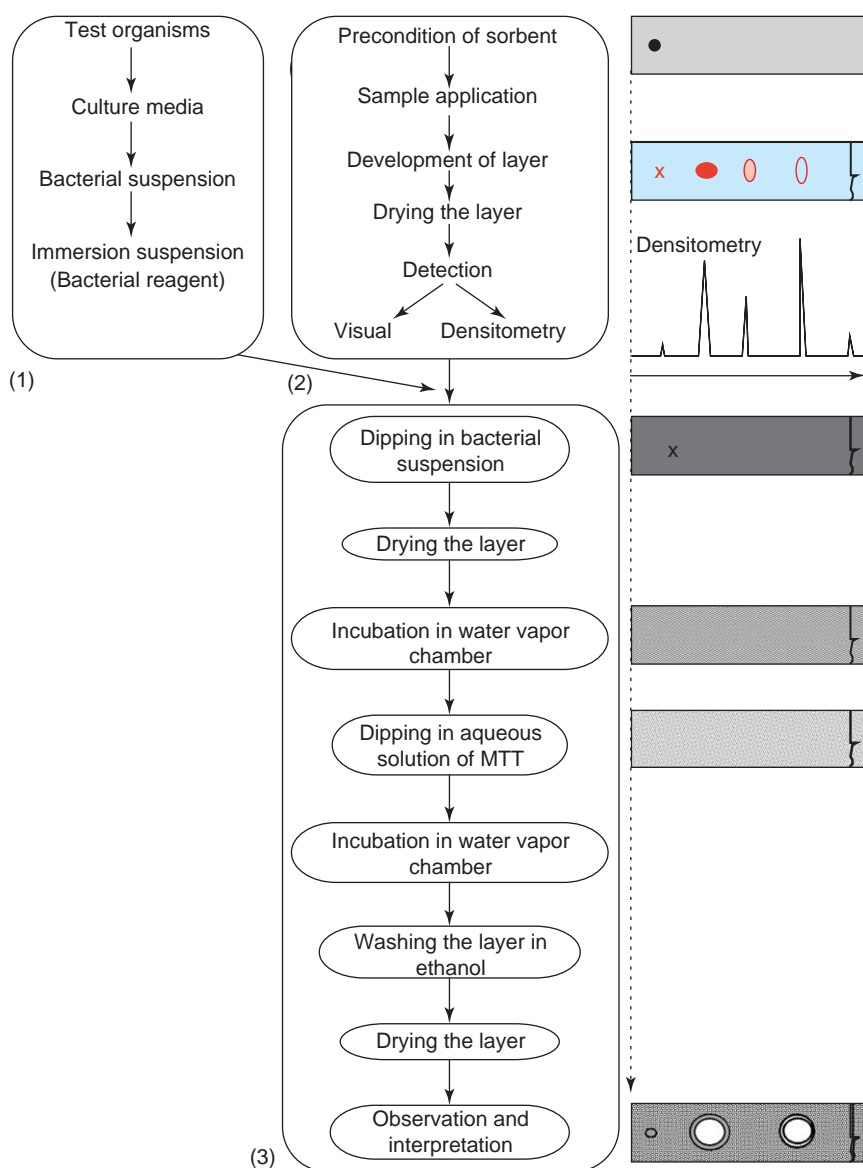

The chromatographic part of the assay is affected by solvents, additives, eluents, sorbents, spot volume, sample application, development mode, spot or band broadening, resolution of the separated compounds, the analytical detection, and the derivatization.

The microbial part of the assay depends greatly on the origin, contamination, pH of the samples, the composition of the culture medium, the chemical character of the analyzed material, the immersion suspension, the incubation temperature, the incubation time, and the visualization of the inhibition zones.

The components of the elution or extraction solutions are essential. Solvents can contain impurities and/or stabilizers, which might inhibit bacterial or fungal growths. Also, solvents or their residues in the adsorbents can alter results (e.g., traces of acetic acid remaining in the adsorbent inhibit bacterial growth). Tetrahydrofuran is not a suitable chromatographic solvent because even in a minute amounts it inhibits bacterial growth. It is beneficial if the mobile phase contains highly volatile solvents, so they can be completely removed before the microbial assay. This is not the case with most of the acids and bases. The good eluents used in direct bioautography does not disturb the microbial detection.

The selection of the appropriate adsorbent is not simple. The adsorbent has to fulfill the requirements of the chromatographic and the microbial processes. Normally, precoated silica gel plates are used as it contains sufficient binding power. The TLC technique mainly uses silica gel. It is also very promising to use a water-resistant glass plate. In special circumstances other adsorbents (e.g., alumina for gentamicin) are more appropriate. The use of polyamide and cellulose layers for direct bioautography is limited. Precleaning of the chromatographic plates with appropriate solvent is vital.

The insoluble compounds in the bands can crystallize after drying. This reduces the sensitivity of the assay considerably. Drying of compounds on silica gel plates can be also detrimental for some fungicides, probably because of their inherent chemical reactivity. Very concentrated sample loads, in terms of

**Figure 3** Implementation of the direct bioautography assay.

material per unit area, are required for the greatest sensitivity after visual detection. In the case of natural substances the sensitivity of direct bioautographic assay was most successful on silica gel layers. The most efficient detection system uses high-performance TLC layers with *Bacillus subtilis*. The detection limit can be determined by measuring of the diameter of the clear zone (inhibition ring). The values of the minimum detectable dose can be determined similarly to conventional TLC.

### Optimization of Direct Bioautography

The key factors in the optimization of the assay are the quality of the bacterial suspension and the conditions of the TLC incubation.

Frequent practice is the use of the overnight cultures, like in the case of *B. subtilis*, or 6-h cultures, like in the case of *E. coli*. The optical density (OD) (absorbance) of the bacteria suspension is varied. It is recommended to be between 0.40 and 0.60, which represents  $\sim 4 \times 10^7$  cells  $\text{ml}^{-1}$ .

It is important to ensure the maximum metabolic activity of the microbe suspension. The ATP (adenosine triphosphate) content reflects the metabolic activity of cells. Thus, the measurement of ATP content is a good indicator of the viability of bacteria. The measured ATP content must be expressed on the basis of one of the cellular attributes (protein content or cell number). The bacterial suspensions are the most suitable for coating the TLC plates when their growth is in the exponential log phase, and their OD

is between 0.2 and 0.5. When the OD is higher than this, the cell's activity, which is mirrored by the ATP content, is already in decline.

The surface of the sorbent material does not provide good living conditions for microbes. The growth medium adhered to the silica particles in TLC acts a source of nutrients for the test bacteria.

The relationship between the ATP and the protein contents is crucial. An optimum ratio between these two parameters is required for the successful microbial test of the plate. The best stage of growth shows high ATP content, without protein degradation. Only the metabolically active bacteria can convert the tetrazolium salt.

As a rule, higher sensitivity of the assay may be obtained by shorter incubation times for chromatoplates. The optimum incubation time (when the culture is in the exponential log phase) for Gram-positive sporeforming test bacteria is between 8 and 12 h while for Gram-negative enterobacterial bacteria is between 3 and 6 h.

In summary, the principles of optimization are the following:

1. The plate must be coated with a bacterial culture at its maximum ATP activity.
2. The immersion suspension must contain a large number of vigorous microbes.
3. The higher OD value does not necessarily guarantee better detection.
4. By mixing bacterial cultures in different stages of growth in order to achieve the optimum OD value for the suspension is not acceptable.

## Introduction

Bioluminescence ('living light') is the name given to the visible light emission from living organisms. It is

widely distributed in nature (~666 genera from 13 phyla) and some representative examples of bioluminescent organisms are shown in **Table 1**. In the marine environment, it has been estimated that in the dimly lit mid-ocean between 200 and 1200 m ~95% of fish and 86% of shrimps and squid are bioluminescent. In surface water <10%, and in the abyssal

**Table 1** Examples of bioluminescent organisms

Organism	Common name	Wavelength of light emission (range or max) (nm)
<i>Aequorea aequorea</i>	Jelly fish	500–523
<i>Agyroplecus affinis</i>	Hatchet fish	~480

depths <25% of organisms are bioluminescent. The phenomenon of bioluminescence has been known since ancient times. Aristotle (384–322 BC) described the luminescence of fungi and dead fish in *De Anima*, and in 1668 Robert Boyle established the requirement for oxygen in bioluminescent reactions. Dubois in the late 1880s performed experiments with hot and cold water extracts of fire beetle and extracts of clam, and showed that light emission resulted when the hot and cold water extracts were mixed together in the presence of oxygen. He named the heat-labile (cold water) extract luciferase, and the heat-stable (hot water) extract luciferin. These generic names have come to be used for the enzymes (luciferase) and substrates (luciferin) in bioluminescent reactions. However, it must be noted that luciferases and luciferins from different organisms differ widely in chemical structure and composition (Table 2); for example, luciferins include aldehydes, imidazopyrazines, benzothiazoles, tetrapyrroles, and flavins (Figure 1). The function of bioluminescence is diverse and includes luring prey (Midshipman fish, *Porichthys*), camouflage (Hatchet fish), schooling

## Principles

In a bioluminescent reaction, a luciferase or a photoprotein catalyzes a reaction that produces chemically excited intermediates that decay to the electronic ground state and release energy in the form of visible light (390–750 nm). The efficiency of the overall process is characterized by a quantum yield for bioluminescence ( $\phi_{BL}$ ). This is the product of the fraction of the molecules reacting  $\times$  fraction of molecules entering the bioluminescence pathway that become electronically excited  $\times$  fluorescence quantum yield of the excited state product. Most bioluminescent reactions are relatively inefficient (e.g., for the *Renilla* luciferin–luciferase reaction *in vitro*,  $\phi_{BL} = 0.05$ ); however, the firefly reaction is unique in having a quantum yield for bioluminescence close to unity ( $\phi_{BL} = 0.88$ ). The intensity of light emission is  $> 2 \times 10^8$  photons  $s^{-1} cm^{-2}$  in the Flashlight fish (*Photoblepharon*) and  $> 2 \times 10^9$  photons  $s^{-1} cm^{-2}$  in the dinoflagellate *Gonyaulax*. Studies of bioluminescent spectra reveal that the maximum light emission of most deep-sea species is in the range 450–490 nm (blue), that that of coastal species is in the range 490–520 nm (green), and that terrestrial and freshwater species emit in either the yellow (550–580 nm) or green (510–540 nm) part of the spectrum.

A common feature of bioluminescent reactions is that they are oxidation reactions. Only oxidation reactions can provide the energy needed to produce high-energy states that will emit photons when they decay to the ground state (e.g., the energy required to produce blue light at 450 nm is 265.4 kJ mol<sup>-1</sup>). One

**Figure 1** Structures of luciferins: (A) limpet luciferin (e.g., *Latia*); (B) firefly luciferin (e.g., *Photinus*); (C) dinoflagellate luciferin (e.g., *Gonyaulax*); (D) coelenterate luciferin (e.g., *Renilla*, *Aequorea*); (E) bacterial luciferin (e.g., *Vibrio*, *Photobacterium*).

of the most important recent developments has been the elucidation of the molecular biology of bioluminescence and the cloning of many of the genes that encode luciferases and photoproteins (Table 2). These genes, particularly the firefly gene (*luc*), have been used as alternatives to the chloramphenicol acetyl-transferase gene (CAT) as reporter genes for the study of gene regulation and expression. Also, pairs of bioluminescent genes (e.g., firefly and *Renilla* luciferase) have been employed for two-color monitoring of the expression of two different genes. Genes for bioluminescent proteins have been transferred to and expressed in different bacteria, yeast, mammalian cells, transgenic mice, and plants. They

have also been fused with genes encoding other proteins and the fused gene expressed to produce a bioluminescent fusion protein (e.g., apoaequorin + IgG heavy chain, bacterial luciferase + interferon). The fusion proteins have found use as conjugates in immunoassay and have replaced conjugates prepared by conventional covalent coupling techniques.

## Firefly

The North American firefly, *Photinus pyralis* (order Coleoptera, family Lampyridae), has light organs on

the ventral surface of the sixth and seventh abdominal segments. The light emission arises from the firefly luciferase (EC 1.13.12.7) catalyzed ATP-dependent oxidative decarboxylation of firefly luciferin (reaction [I]). The reaction proceeds in two stages; first an AMP–luciferin complex is formed and then this is oxidized by oxygen to form the excited-state oxyluciferin via a dioxetanone intermediate:

A yellow–green light emission (565 nm max) is produced at neutral pH, but at low pH and in the presence of doubly charged ions such as  $\text{Pb}^{2+}$ ,  $\text{Hg}^{2+}$ ,  $\text{Zn}^{2+}$ , and  $\text{Cd}^{2+}$ , the light emission is shifted to longer wavelengths (610–615 nm).

Firefly luciferase is a dimer comprising two identical 62 kDa subunits (one active site per dimer, pH optimum 7.75). It has a binding site for  $\text{MgATP}^{2-}$ , and the  $K_m$  for luciferin is  $1\text{--}10 \mu\text{mol l}^{-1}$  and for  $\text{MgATP}^{2-}$  it is  $0.25 \text{ mmol l}^{-1}$ . The product of the reaction, oxyluciferin, is an inhibitor ( $K_i = 0.23 \mu\text{mol l}^{-1}$ ), as are pyrophosphate, free ATP, and various anions ( $\text{SCN}^- > \text{I}^- > \text{ClO}_4^- > \text{acetate}$ ).

*In vitro* the light emission is in the form of a rapid flash ( $\sim 300$  ms to reach peak). Detergents (e.g., Triton X-100 at concentrations above the critical micelle concentration) and polymers (e.g., poly(ethylene glycol) 6000) modify the kinetics to a protracted glow and this has been interpreted as due to selective removal of the inhibitory oxyluciferin product by micelles. Firefly luciferase can be covalently immobilized to solid supports such as Sepharose and nylon and still retain enzymatic activity. Likewise, it can be covalently coupled to small molecules such as biotin and methotrexate. However, attempts to link the enzyme to large molecules, e.g., immunoglobulin G (IgG), to produce conjugates that retain firefly luciferase activity have been unsuccessful. Firefly luciferase is one of the most hydrophobic proteins known, and this may explain the difficulties encountered in preserving activity during chemical modifications. Enzyme activity is inhibited by anesthetics (e.g., ether, chloroform) and this is attributed to a similarity between the hydrophobic binding site on luciferase and the protein-binding site for general anesthetics.

## Click Beetle

The Jamaican click beetle, *Pyrophorus plagiophthalmus* ('kitty boo'), is capable of emitting different colors of light from the pair of light organs on the surface of the head (green, yellow–green), and the

single organ on the ventral surface of the abdomen (yellow–green to orange). The luciferin in this species is exactly the same as the luciferin from the firefly. The different colors of bioluminescence arise from different luciferases. Four have been characterized (green, 546 nm; yellow–green, 560 nm; yellow, 578 nm; and orange, 593 nm). The genes encoding these luciferases have been cloned and the amino acid sequences of the four luciferases show 94–99% identity, but <50% identity with firefly luciferase.

## Bacteria

Luminous bacteria (Gram-negative motile rods) are widely distributed and the most abundant light-emitting organism. Luminous bacteria are classified into three genera, *Vibrio*, *Photobacterium*, and *Xenorhabdus*. They are found principally in a marine environment, but freshwater (e.g., *Vibrio albenis*) and terrestrial species (e.g., *Xenorhabdus luminescens*) are also known. In the marine habitat, luminous bacteria are free-living, or as symbionts in fish (e.g., teleost fish + *Photobacterium leiognathi*).

The reactions leading to light emission involve a fatty acid reductase complex (reaction [II]), NADH:FMN oxidoreductase (EC 1.6.99.3) or NADPH:FMN oxidoreductase (EC 1.6.99.1) (reaction [III]), and bacterial luciferase (EC 1.14.14.3) (reaction [IV]). The  $K_m$  values for NADH and NADPH with the oxidoreductases of the appropriate selectivity are 23 and  $22 \mu\text{mol l}^{-1}$ , respectively. For luciferase the  $K_m$  for  $\text{FMNH}_2$  is  $0.3 \mu\text{mol l}^{-1}$ . In the luciferase reaction enzyme-bound  $\text{FMNH}_2$  is oxidized to a 4a-peroxy flavin intermediate and this reacts with tetradecanal to form a stable intermediate that decays slowly with the emission of light. The aldehyde (tetradecanal) is oxidized to tetradecanoic acid:

The genes (*lux* genes) encoding luciferase and the other proteins involved in the bioluminescent reaction have been cloned. Luciferase subunits are coded

**Figure 2** Bioluminescence marine bacteria *Beneckea harveyi*. (Reproduced with permission of LJ Kricka, Hospital of the University of Pennsylvania, Philadelphia, USA.)

by the *luxA* and *luxB* genes, and the fatty acid reductase complex is coded by the *luxCDE* genes.

A feature of the growth of bioluminescent marine bacteria is that light emission lags behind cell growth **Figure 2**. One reason for this lag is the requirement for an autoinducer to accumulate in the medium. The autoinducers in *Vibrio fischeri* and *Vibrio harveyi* have been identified as  $\beta$ -caproylhomoserine lactone and  $\beta$ -hydroxybutyrylhomoserine lactone, respectively.

Marine bacterial luciferase can be immobilized on to a variety of solid supports (e.g., Sepharose, nylon) and it has also been coimmobilized with NAD(P)H:FMN oxidoreductase. The close proximity of the two enzymes leads to efficient channeling of FMNH<sub>2</sub> produced by the oxidoreductase to the luciferase. More extensive coupled coimmobilized systems have been prepared in which all of the enzymes in the enzymatic conversion of glucose to alcohol were coimmobilized with bacterial luciferase and the oxidoreductase, and the bioluminescent enzymes were used to monitor different stages in the biotransformation of glucose.

## Other Systems

### Aequorea

The hydrozoan jellyfish, *Aequorea forskalea*, contains the Ca<sup>2+</sup>-activated photoprotein aequorin (as a family of isoaequorins). Aequorin is composed of apoaequorin and a prosthetic group (coelenterazine). *In vitro* this can be prepared by incubating apoaequorin with coelenterazine in the presence of oxygen. Light emission (460 nm max, rapid flash) is triggered by simply adding a source of Ca<sup>2+</sup>; there is no requirement for oxygen because the luciferin has already reacted with oxygen to form a stable peroxide ('precharged'). Aequorin can also be triggered by

other metal ions (Sr<sup>+</sup>, Ba<sup>2+</sup>, La<sup>3+</sup>, Yb<sup>3+</sup>). The main application of this protein has been as an intracellular calcium indicator.

### Gonyaulax

The dinoflagellate *Gonyaulax polyedra* produces brief flashes of light (<0.1 s) that originate from numerous (~400) small (0.5  $\mu$ m) organelles caused scintillons. The scintillons contain an open tetrapyrrole-type luciferin bound to a luciferin-binding protein (dimer, 72 kDa subunits). Change in the pH from 8 to 5.7 releases the luciferin, which then reacts with luciferase (420 kDa) to produce a flash of light at 479 nm. The genes encoding both the luciferase and the luciferin-binding protein have been isolated and cloned. An interesting feature of this bioluminescent organism is that light emission exhibits a circadian rhythm in which cells emit light at night but not during the daytime. This is achieved by translational control of luciferin and luciferin-binding protein synthesis (mRNA levels for these proteins are constant).

### Renilla

The sea pansy, *Renilla reniformis*, contains a luciferase ( $K_m$  luciferin = 30 nmol l<sup>-1</sup>, pH optimum ~7.6), a luciferin-binding protein (18.5 kDa, two Ca<sup>2+</sup> binding sites) that sequesters and then releases luciferin, and a green fluorescent protein (dimer, 34 + 53 kDa,  $\epsilon = 4.3 \times 10^4$  mol l<sup>-1</sup> cm<sup>-1</sup>, fluorescence quantum yield = 0.7–0.9). Bioluminescence arises from the sequence of reactions shown in reactions [V]–[IX], and involves a charge transfer between green fluorescent protein and the excited-state coelenterate oxyluciferin. The gene for *Renilla* luciferase has been cloned and used to prepare a recombinant luciferase for investigational use. In addition, the gene for green fluorescent protein (*gfp*), isolated from the bioluminescent *Renilla*, has become widely used for gene expression, both *in vivo* and *in vitro*:

(PAP = adenosine 3',5'-diphosphate; PAPS = adenosine 3'-phosphate 5'-phosphosulphate)

## Instrumentation

Instruments for measuring light emission (luminometers) utilize a range of detectors, including film (photographic or X-ray), photomultiplier tubes (in current or single-photon-counting mode), silicon photodiodes, and charge-coupled device (CCD) cameras. The most sensitive detection of light emission is achieved using single-photon-counting techniques. Luminometers vary in size and complexity from simple portable luminometers for use in the field to automated high-throughput instruments capable of measuring light emission from many hundreds of tubes. The kinetics of light emission from some bioluminescent reactions is in the form of a flash of light and thus some luminometers are equipped with injectors to initiate the reaction directly in front of the detector. For specialized applications, such as immunoassay, automatic analyzers that incorporate a luminometer have been produced. These instruments automate sampling, reagent addition, washing, incubation, and aspiration steps in an assay, and finally the initiation and measurement of the light emission.

## Applications

The sensitivity and versatility of bioluminescent reactions has led to a wide range of applications (Table 3). Three bioluminescent reactions, firefly luciferase, marine bacterial luciferase, and the aequorin reaction, dominate and account for more than 90% of the applications. The versatility of bioluminescent reactions stems from the dependence of the reactions on key substances such as ATP (firefly reaction), NAD/NADH (marine bacterial reaction), and metal ions such as calcium (aequorin), and the fact that ATP and NAD can in turn be coupled to kinases and dehydrogenases to measure either the enzyme or its substrate.

### Clinical

There is a diverse range of clinical applications for bioluminescence; however, few have found widespread use in routine clinical laboratories. Detection of ATP as an indicator of cell mass is the most important clinical use of bioluminescence (reaction

[X]). The firefly assay detects 80 fmol ATP, and it is now possible to detect the ATP from fewer than 10 bacterial cells. The presence of abnormally increased numbers of bacteria in urine (bacteriuria) can be detected rapidly by this technique. The bioluminescent detection of ATP using the firefly reaction is also useful in drug susceptibility testing and this is now being used to assess the chemosensitivity of tumor tissue to cancer drugs (a susceptible tumor will not grow in the presence of the appropriate drug and thus the number of cells and hence the ATP

concentration will be low):

The marine bacterial bioluminescent system when coupled to 7- $\alpha$ -hydroxysteroid dehydrogenase provides a very sensitive (0.5 pmol) and precise method for serum bile acids according to the analytical scheme shown in reaction [XI]. This assay is typical of bioluminescent coupled enzyme assays for either a dehydrogenase enzyme or its substrate.

In order to improve the efficiency of the coupled enzymes, they are used as a coimmobilized preparation (coimmobilized on Sepharose beads). The assay is very simple to perform; a serum sample containing bile acids is mixed with a suspension of the coimmobilized enzymes and the coreactants (NAD, decanal, FMN). Light emission commences almost immediately and the maximum intensity is measured and related to the concentration of bile acid in the sample. Similar reactions can be performed using soluble enzymes; for example, the distribution of metabolites in tissue sections can be determined by incubating the section with a mixture of enzymes and cofactors (e.g., lactate is detected using a mixture of lactate dehydrogenase, bacterial luciferase/oxidoreductase, decanal, FMN, and NAD) and imaging the light emission directly with a CCD or similar type of photon camera:

### Immunoassay and Nucleic Acid Probe Assays

Firefly, marine bacterial, *Renilla* and *Vargula* luciferase, and the photoprotein apoaequorin have all been employed as labels in immunoassays (Table 3). An example of the experimental design for a competitive bioluminescent immunoassay for the drug methotrexate based on a firefly luciferase label is shown in reaction [XII]:

The other major application for bioluminescent reactions is the detection of conventional enzyme

labels. Alkaline phosphatase can be detected down to 10 zmol ( $10 \times 10^{-21}$  mol) using a firefly D-luciferin-O-phosphate substrate. Released luciferin is detected with a mixture of firefly luciferase, ATP, and magnesium ions. Glucose 6-phosphate dehydrogenase has been used as a label in both immunoassay and DNA probe assays. It is detected by quantifying the NADH formed in its reaction with NAD and glucose 6-phosphate using the marine bacterial luciferase/NADH:FMN oxidoreductase reaction.

### Reporter Genes

The gene for firefly luciferase (*luc*) has become one of the most popular reporter genes because the gene product, firefly luciferase, can be detected quickly and sensitively (detection limit for luciferase  $< 10^{-20}$  mol). In many applications it is replacing the more conventional chloramphenicol acetyltransferase gene (CAT) in reporter gene studies. A construct comprising the entire set of marine bacterial genes required for light emission, *luxCDEAB*, can also be assembled and used as a reporter cassette. However, it is the gene for green fluorescent protein (*gfp*) that has become one of the most important reporter genes and is now in widespread use. An advantage of this reporter gene is that it can be visualized using excitation light of the appropriate wavelength (470 nm) without destruction of the cells. Various green fluorescent protein mutants with different light emission maxima in the blue, green, and yellow-green regions of the spectrum provide gene combinations for multicolor analysis.

### Food, Environmental, and Industrial

Most applications for bioluminescence in these three areas are related to the detection of microbes via ATP content using the firefly reaction. Rapid results are very important in many industrial settings, e.g., hygiene monitoring in food production areas, and the rapidity of bioluminescent assays is an attractive and advantageous feature. There is also an increasing number of tests for toxins based on cells containing the *lux* and *luc* reporter genes.

## BLEACHES AND STERILANTS

**M A Busch and K W Busch**, Baylor University, Waco, TX, USA

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Bleaching agents remove or prevent unwanted discoloration of a substrate. Chemical sterilants and disinfectants destroy undesirable microorganisms on contact. This article surveys the more important chemicals that are employed for these purposes and discusses the most important analytical methods that are used for their determination. Because the residual levels of disinfectants following municipal water treatment are subject to governmental regulation, this article gives particular emphasis to the standard methods for determining chlorine residuals in drinking water.

### Major Areas of Use and Application

Bleaching agents are formulations that whiten or lighten a substrate by solubilizing color-producing

substances or by altering their light-absorbing properties. Bleaching agents are used extensively in the pulp and paper industry, the textile industry, and commercial and household laundering.

The chemistry of bleaching agents is predominantly that of oxidizing agents: chlorine ( $\text{Cl}_2$ ) and some of its compounds or peroxygen species such as hydrogen peroxide ( $\text{H}_2\text{O}_2$ ), ozone ( $\text{O}_3$ ), and sodium perborate ( $\text{NaBO}_3$ ). The decolorizing reaction generally involves the removal of chromophoric sites in which electron delocalization over conjugated double bonds has made the substrate capable of absorbing visible light. The bleaching agent will typically react by irreversibly cleaving or adding across these double bonds.

A few bleaching compounds act by chemical reduction; these include sulfur dioxide ( $\text{SO}_2$ ), sulfurous acid ( $\text{H}_2\text{SO}_3$ ), hydrogensulfite ( $\text{HSO}_3^-$ ), sulfite ( $\text{SO}_3^{2-}$ ), and dithionite ( $\text{S}_2\text{O}_4^{2-}$ ), as well as sodium tetrahydroborate (borohydride) ( $\text{NaBH}_4$ ). Their application is primarily in pulp and textile manufacturing, where the bleaching action is thought to occur by reduction of a chromophoric carbonyl group.

Other applications include the bleaching of glues, gelatin, soap, and food products.

Chemical bleaching of textiles (as opposed to bleaching by sunlight, a process known as crofting) had its advent soon after the discovery of the element chlorine by Scheele in 1774. Finding that aqueous solutions of chlorine gas weakened the fiber of textiles, Bertholet experimented with solutions of potassium hypochlorite ( $\text{KOCl}$ ), made by dissolving chlorine gas in a solution of caustic potash ( $\text{KOH}$ ). Labarraque made hypochlorite solutions industrially economic by replacing the more expensive caustic potash with caustic soda ( $\text{NaOH}$ ). The liquid household bleach normally available today is a 5% solution of sodium hypochlorite ( $\text{NaOCl}$ ).

Sterilants are strictly defined by the US Environmental Protection Agency as substances that totally destroy all forms of life, including viruses, bacteria, fungi, and their spores on inanimate surfaces, in water, or in the air. Many substances that render objects microbiologically safe for certain applications (i.e., reduce the level of living microorganisms below some predetermined level) are also commonly referred to as sterilants.

Sterilization can be accomplished by treatment with chemicals, as well as by heat, cold, and radiation. Chemical sterilants are also typically oxidizing agents, and their effectiveness is related to their ability to oxidize the cell wall of the microorganism and to diffuse through the cell wall and disrupt cellular activity. Many of the same substances that act as bleaching agents (Table 1) are also used extensively as sterilants.

Chemical disinfection with chlorine gas was recommended as early as 1801 and was widely installed in British and European hospitals by 1823. Following the discovery of the microbial basis for contagious diseases, Robert Koch (1881) demonstrated that hypochlorites were effective in killing bacteria. In 1905, following an outbreak of typhoid fever in

London, continuous chlorination of the public water supply was inaugurated. Chemical disinfection of a public water supply was first practiced in the United States in 1908, and since that time has been a routine part of municipal water treatment. Chemical disinfectants are also used extensively in the production of bottled water and the manufacture of containerized beverages of all types, in the treatment of waste water, and in the treatment of water in swimming pools and spas.

## Chemicals Used as Bleaches and Sterilants

A comprehensive discussion of the analytical chemistry of bleaches and sterilants is complicated by the diversity of chemicals that are employed. The following is a brief survey of some of the more important chemicals that are used for these purposes.

Modern chlorine-based bleaching agents include elemental chlorine ( $\text{Cl}_2$  gas), a variety of hypochlorites ( $\text{OCl}^-$ ), certain *N*-chlorinated organic compounds, and chlorine dioxide ( $\text{ClO}_2$ ). The first three bleaching agents all hydrolyze to produce hypochlorous acid in aqueous solution, according to the equilibria in reactions [I]–[III]

where R and R' represent a variety of substituents.

Figure 1 shows the effect of pH on the chemical form of dissolved chlorine in aqueous solution for a fixed chloride ion concentration of  $1 \times 10^{-3} \text{ mol l}^{-1}$ . The neutral hypochlorous acid molecule, which is thought to be more effective in penetrating cell walls than the charged hypochlorite ion, has a disinfecting ability that is greater than that of  $\text{OCl}^-$  by 2 orders of magnitude. As a result, an aqueous solution of chlorine will have its maximum disinfecting ability over a pH range from  $\sim 2$  to 7.

Solutions of hypochlorites and hypochlorous acid are subject to gradual deterioration, forming chlorite ( $\text{ClO}_2^-$ ) and sometimes chloride ( $\text{Cl}^-$ ) and oxygen ( $\text{O}_2$ ) over a period of time. In general, the lower the pH, the less stable the solution. (Solid preparations of hypochlorite salts are quite stable if kept dry and cool.)  $\text{HOCl}$  and  $\text{ClO}^-$  react strongly with organic

**Table 1** Oxidizing strengths of some typical bleaching agents and disinfectants as represented by their standard reduction potentials

Compound	Standard reduction potential (V)	Half-cell
$\text{Cl}_2$	+1.3595	$\text{Cl}_2 + 2\text{e}^- \rightarrow 2\text{Cl}^-$
$\text{Br}_2$	+1.0652	$\text{Br}_2 + 2\text{e}^- \rightarrow 2\text{Br}^-$
$\text{I}_2$	+0.5355	$\text{I}_2 + 2\text{e}^- \rightarrow 2\text{I}^-$
$\text{O}_3$	+2.07	$\text{O}_3 + 2\text{H}_3\text{O}^+ + 2\text{e}^- \rightarrow \text{O}_2 + 3\text{H}_2\text{O}$
$\text{ClO}_2$	+1.91	$\text{ClO}_2 + 2\text{H}_2\text{O} + 2\text{e}^- \rightarrow \text{Cl}^- + 4\text{OH}^-$
	+0.95	$\text{ClO}_2 + \text{e}^- \rightarrow \text{ClO}_2^-$
$\text{H}_2\text{O}_2$	+1.776	$\text{H}_2\text{O}_2 + 2\text{H}_3\text{O}^+ + 2\text{e}^- \rightarrow 4\text{H}_2\text{O}$

**Figure 1** Distribution diagram for aqueous chlorine in a closed system at 25°C with  $[\text{Cl}^-] = 1 \times 10^{-3} \text{ mol l}^{-1}$ . The fraction present in a given form ( $\alpha$ ) is equal to the concentration of the given species divided by  $C_T$  where  $C_T = [\text{Cl}_2] + [\text{HOCl}] + [\text{OCl}^-]$ .

matter and, for maximum effectiveness, organic contamination must be removed prior to use.

Examples of *N*-chlorinated organic compounds that gradually hydrolyze to HOCl include chloramine-T (*N*-chloro-*p*-toluenesulphonamide) (1), *N*-chlorohydantoin (2), and various chlorinated isocyanurates (3). They are mainly employed as disinfectants, because their low solubility and/or hydrolysis in water affords poor bleaching ability. The one exception is sodium dichloroisocyanurate dihydrate, which is the most water soluble, the fastest to dissolve, and the least hazardous.

Chlorine dioxide is fast replacing aqueous  $\text{Cl}_2$ , particularly in pulp and paper manufacture, because the reaction of  $\text{ClO}_2$  with organic materials does not appear to form carcinogenic trihalomethanes (THMs) as side-products and because  $\text{ClO}_2$  is 10

times more effective as a disinfectant under high chlorine demand. Chlorine dioxide is an explosive gas and is usually prepared onsite by the hydrolysis of an alkali-stabilized solution of sodium chlorite ( $\text{NaClO}_2$ ) (see reactions [IV] and [V]):

Somewhat higher yields are afforded by reacting sodium chlorite with chlorine gas (reaction [VI]):

Excess chlorine must be removed from the mixture prior to use to prevent THM formation. Somewhat larger amounts of chlorine dioxide, such as needed in pulp processing and textile bleaching, are generally prepared by reduction of chlorate with hydrochloric acid (reactions [VII] and [VIII]):

Hydrogen peroxide and other peroxy compounds derived from hydrogen peroxide are also used as bleaching agents. These compounds all contain the peroxide linkage ( $-\text{O}-\text{O}-$ ). Liquid solutions of hydrogen peroxide are commercially available (30–35%, 50%, or 65–70% by weight); however, stable solid peroxy compounds that hydrolyze in solution to give hydrogen peroxide offer improved

stability and convenience in handling. Typical among this class of solid bleaching agents (so-called safety bleaches) is sodium perborate, which is formed by reacting borax (sodium metaborate) with hydrogen peroxide in the presence of base

(reaction [IX]):

Hydrogen peroxide is a very weak acid and is relatively stable in acidic solution. Bleaching is performed in alkaline solution, where part of the hydrogen peroxide is converted to the perhydroxyl anion ( $\text{HO}_2^-$ ), believed to be the active bleaching agent (reaction [X]):

Disproportionation to water and oxygen is markedly accelerated by the presence of heavy metals, and metal chelating agents are often added to solutions of  $\text{H}_2\text{O}_2$  as stabilizers.

Concern over the adverse health effects of trace amounts of THMs produced during the chlorination of drinking water has led to the use of nonchlorinated disinfection agents, such as ozone ( $\text{O}_3$ ), in the treatment of domestic water, particularly in Europe. Ozone has not been extensively employed in the United States because it is difficult to maintain an active residual once the water leaves the treatment plant. Ozone gas is also used in hospitals to sterilize instruments and surgical dressings.

Ozone decomposes rapidly to oxygen ( $\text{O}_2$ ) and must be generated on demand, in close proximity to the utilization site. Ozone is generated by passing air or oxygen through a high-voltage corona discharge. Aqueous solutions are prepared by bubbling the gas through a column of water.

Sulfur dioxide ( $\text{SO}_2$ ) is a gas, formed by burning sulfur in air. When dissolved in water,  $\text{SO}_2$  forms sulfurous acid, a complex mixture of  $\text{SO}_2$ ,  $\text{H}_3\text{O}^+$ ,  $\text{S}_2\text{O}_3^{2-}$ , and  $\text{HSO}_3^-$ . All of these species are good reducing agents, making the bleaching effect independent of pH over the range 3–10.

## Survey of Analytical Methods

In industrial operations like pulp and paper manufacturing and textile bleaching, the selection of analytical methodology is largely dictated by process analytical and quality control requirements. By contrast, the methods used for the determination of residual levels of disinfectants in drinking water are subject to regulation by national and local governments. As a result, 'standard methods' for these procedures, which are recognized by courts in any legal action, are continuously being developed and revised. Up-to-date, detailed procedures for the determination of residual levels of disinfectants in

drinking water can be found in the latest publications and reports from the sources listed below:

- 'Standard Methods for the Examination of Water and Wastewater', published jointly by the American Public Health Association, the American Water Works Association, and the Water Pollution Control Federation, Washington, DC, USA.
- 'US Environmental Protection Agency', Analytical Reference Service Reports, Municipal Environmental Laboratory, Cincinnati, Ohio, USA.
- 'Standing Committee of Analysts', Department of the Environment, London, UK.
- 'American Water Works Association', Research Foundation Reports, Denver, Colorado, USA.
- 'Guidelines for Canadian Drinking Water Quality', Health and Welfare Canada, Ottawa, Ontario, Canada.

Since these methods can generally be adapted for the analysis of bleaching agents in industrial processes, this article will focus on the standard analytical procedures developed for water analysis.

## Determination of Chlorine Residuals in Drinking Water

Because chlorine-based disinfectants are widely used in water treatment, much effort has been invested in the development of analytical methods for their determination in municipal water samples over the concentration range from 0.001 to  $10 \text{ mg l}^{-1}$  (expressed as  $\text{Cl}_2$ ). The overriding challenge in the development of these procedures has been the need to distinguish between the free and combined forms of residual chlorine. This terminology is highly specific and, in order to clarify the discussion that follows, the definitions of these and other relevant terms are listed below.

- Chlorine demand: free available chlorine (FAC) required to react with all oxidizable species present in the water sample.
- Combined (available) chlorine: total available chlorine in the form of undissociated *N*-chloro compounds that can hydrolyze according to reaction [III].
- Free (available) chlorine: total available chlorine in the form of dissolved  $\text{Cl}_2$  gas, hypochlorous acid ( $\text{HOCl}$ ), and hypochlorite ion ( $\text{ClO}^-$ ).
- Residual chlorine: total available chlorine remaining after reaction of FAC with oxidizable species present in the water sample.
- Total (available) chlorine: total concentration of chlorine-based oxidants in the form of dissolved

$\text{Cl}_2$  gas, hypochlorous acid ( $\text{HOCl}$ ), hypochlorite ion ( $\text{ClO}^-$ ), and  $N$ -chlorinated organic compounds that can hydrolyze according to reaction [III].

When chlorine is added to a surface water or groundwater, a number of species present in the water can consume chlorine, and such reactions are said to constitute the chlorine demand of the water. Reactions with inorganic species such as iron, manganese, and sulfides produce chloride ion ( $\text{Cl}^-$ ), which has no residual oxidizing power. However, nitrogenous bases, such as ammonia ( $\text{NH}_3$ ), urea, and amino acids, react to form chloramines and other organically bound chlorine compounds. These combined forms of chlorine (called combined available chlorine) typically retain some disinfectant properties, but are generally weaker than solutions containing hypochlorous acid and hypochlorites in an uncombined state (FAC). The combined as well as free forms of available chlorine that remain after the chlorine demand of the water has been satisfied constitute the chlorine residual.

An FAC residual is regarded by the US Environmental Protection Agency as a sign of adequate disinfection. The problem encountered in ensuring that water leaving the treatment plant has been treated with enough chlorine to leave an FAC residual is illustrated by breakpoint chlorination. In breakpoint chlorination, dissolved chlorine is added to the water in a stepwise manner to determine the chlorine demand and to allow for the formation of chloramines.

Figure 2 is an idealized plot of residual chlorine as a function of the chlorine dose added to the water sample that contains only ammonia. Initially, addition of chlorine causes the rapid formation of monochloramine ( $\text{NH}_2\text{Cl}$ ), and the chlorine residual rises. A maximum in the curve occurs at a  $\text{Cl}_2/\text{NH}_3$  molar ratio near 1, where residual chlorine is present only as monochloramine and some unstable dichloramine ( $\text{NHCl}_2$ ). At a higher chlorine dose, nitrogen gas ( $\text{N}_2$ ), nitrate ( $\text{NO}_3^-$ ), and chloride are formed (reactions [XI] and [XII]),

causing the residual chlorine to decline. Finally, when all of the ammonia has been consumed, a minimum (breakpoint) is reached. At this breakpoint, the chlorine demand of the water has been completely satisfied, and further addition of chlorine causes the chlorine residual (now present as FAC) to increase linearly.

Since governmental regulations specify an FAC residual for adequate disinfection, accurate analytical

**Figure 2** Idealized breakpoint chlorination curve showing chlorine residual as a function of chlorine dose for a water sample at pH 7 that contains only ammonia at a concentration of 1 mg nitrogen (as  $\text{NH}_3$ ) per liter.

methods are required for the determination of FAC at levels less than  $10 \text{ mg l}^{-1}$  in the possible presence of chloramines. If combined chlorine is measured along with free chlorine, the true FAC will be overestimated, and the disinfectant level may be inadequate.

Although no ideal method exists, at present, that can distinguish between free and combined chlorine without interference, analytical methods based on amperometry and the use of  $N,N$ -diethyl- $p$ -phenylene diamine (DPD) are the most frequently employed in water analysis. With both of these methods, FAC is first determined in the absence of iodide ( $\text{I}^-$ ). Iodide can then be added to the solution, and the iodine (present as triiodide ion,  $\text{I}_3^-$ ), formed from the oxidation of iodide by combined chlorine, is determined.

**Methods using DPD** DPD is reversibly oxidized to a magenta-colored cation radical known as a Wüster cation [XIII]:

This reagent has replaced neutral orthotoluidine as the indicator in the standard titrimetric determination of FAC by ammonium iron(II) sulfate ((NH<sub>4</sub>)<sub>2</sub>Fe(SO<sub>4</sub>)<sub>2</sub>) (reaction [XIV]):

In the DPD procedure for FAC, the titration is continued until the red color of the indicator disappears. Because mono- and dichloramines hydrolyze slowly in solution to release hypochlorous acid (reaction [III]), titrations must be carried out rapidly to reduce the interference of combined chlorine.

The concentration of the Wüster cation produced by reaction with FAC can also be determined spectrophotometrically at 515 nm. The absorbance should be measured within 1 min following the addition of DPD reagent to avoid interference of combined chlorine. Calibration standards for the spectrophotometer can be prepared from previously standardized chlorine solutions (by titration with ammonium iron(II) sulfate) or by using standardized potassium permanganate (KMnO<sub>4</sub>) solutions to develop the DPD color.

Both turbidity and colored water samples can produce an interference in the spectrophotometric procedure. Oxidizing agents such as bromine, iodine, chlorine dioxide, ozone, and oxidized forms of manganese will also interfere with either the titrimetric or the spectrophotometric DPD procedure.

In aqueous solution, the DPD indicator is catalytically oxidized by oxygen when trace metals are present. In the standard method, the DPD solution is mixed with a strong phosphate solution, buffered at pH 6.2, and ethylenediaminetetraacetate (EDTA) is added to complex trace metals. Thioacetamide (CH<sub>3</sub>CSNH<sub>2</sub>) can be added immediately following the addition of DPD to decrease the interference from monochloramine. Addition of mercury(II) chloride (HgCl<sub>2</sub>) to the phosphate buffer has also been found to reduce the interference from monochloramine, presumably by complexation of trace iodide by Hg<sup>2+</sup>.

When both free and combined chlorine are to be measured, the FAC is determined first using an excess of DPD. Potassium iodide is then added to the solution and reacts readily with chloramines to produce I<sub>2</sub>, which, in turn, reacts with part of the excess DPD. If only a small amount of KI is added, monochloramine will be the primary reactant. If an excess of KI is added, both mono- and dichloramine can be made to produce I<sub>2</sub>. Thus, sequential addition of KI to the sample can, in principle, allow the various chlorine fractions to be determined.

**Iodometric methods** Iodometric titrations can be used as reference methods for the determination of total available chlorine at concentrations greater than 1 mg l<sup>-1</sup> (as Cl<sub>2</sub>). In this method, an excess of KI is added to the sample. All oxidizing agents having *E*<sup>o</sup> values much greater than +0.54 V will react to form iodine (present as I<sub>3</sub><sup>-</sup>), which is titrated with a standard solution of sodium thiosulfate (Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub>) (reaction [XV]):

The equivalence point is taken as the volume of titrant required to react with all of the I<sub>3</sub><sup>-</sup> formed. The endpoint can be determined using a starch indicator (i.e., at the disappearance of the blue starch-iodine complex) or by amperometry.

For polluted waters or chlorinated waste waters where residual chlorine is present mainly in the combined form, analytical methods do not need to distinguish between FAC and combined available chlorine. Iodometric titration is not recommended because these water samples typically contain small amounts of reducing agents that can react with, and thereby reduce, the liberated iodine over the course of the titration. In this case, an iodimetric procedure is recommended. Arsenic(III) (as arsenic trioxide, As<sub>2</sub>O<sub>3</sub>) is added to the sample in a known amount that is in excess of the combined chlorine, and unreacted As(III) is titrated with a standard solution of I<sub>3</sub><sup>-</sup> to a starch endpoint (formation of a blue color).

**Amperometric methods** Amperometric methods are based on the measurement of current produced in an electrochemical cell at an appropriate applied voltage. **Figure 3** shows a typical cell employed for the amperometric determination of dissolved chlorine, which consists of a reference electrode, whose potential is fixed, and a working electrode, whose potential can be adjusted. If a reducible substance is present in the cell, and the cell potential is sufficiently high, the diffusion current will be proportional to the concentration of reducible species.

In amperometric titrations, the diffusion current is plotted versus the volume of titrant added to give a titration curve consisting of two straight-line segments. **Figure 4** corresponds to the titration of a reducible analyte with a titrant that is not reducible. The titrant volume corresponding to the intersection of the two straight-line segments is taken as the endpoint.

In the amperometric determination of dissolved chlorine (**Figure 3**), an Ag/AgCl reference electrode is

**Figure 3** Amperometric titration apparatus for the determination of dissolved chlorine.

**Figure 4** Amperometric titration curve showing diffusion current versus titrant volume for a reducible analyte and a titrant that is not reducible.

employed, and a spontaneous cell is formed between the platinum electrode (reaction [XVI]) and the reference electrode (reaction [XVII]):

$$E_{\text{ox}}^\circ = -0.222 \text{ V} \quad [\text{XVII}]$$

$$E_{\text{cell}}^\circ = +1.138 \text{ V} \quad [\text{XVIII}]$$

In these equations, the reactions have been represented in terms of standard-state conditions. The true voltage will be somewhat less than that shown in reaction [XVIII] because the  $\text{Cl}_2$  is present in solution and its vapor pressure will be much less than 1 atm, as implied for standard-state conditions. Nevertheless, it is apparent that the voltage produced by this spontaneous cell is more than sufficient to provide limiting current conditions at the platinum electrode. However, most standard methods suggest that +200 mV be applied to the platinum electrode to improve sensitivity (Figure 3). Amperometric titration is the standard method for comparison of accuracy in determining residual chlorine in drinking water. FAC is determined by titration with a standard solution of As(III) (in the form of phenylarsine oxide,  $\text{C}_6\text{H}_5\text{AsO}$ ) at a pH between 6.5 and 7.5. In this pH range, combined chlorine reacts slowly. Total chlorine may be determined by addition of KI to the sample, followed by amperometric titration of the iodine (liberated by the free and combined forms of chlorine) using a standard solution of phenylarsine oxide.

By comparison with spectrophotometric procedures, amperometric methods require somewhat greater skill. The solution must be well mixed and contain sufficient inert supporting electrolyte to reduce the ohmic potential gradients that interfere with the development of a uniform diffusion layer through which the electroactive species must diffuse in order to reach the working electrode. For accurate work, however, care must also be taken to avoid volatilization losses of chlorine from solution by mechanical stirring.

**Other spectrophotometric methods** Other methods for the determination of dissolved chlorine include the use of leuco crystal violet and syringaldazine as color-developing reagents. In the leuco crystal violet method, a colorless precursor (leuco crystal violet) is oxidized to crystal violet (reaction [XIX]), which has an absorption maximum at 588 nm. Interference from combined available chlorine can be avoided if the test is carried out within 5 min of indicator addition. Total chlorine determination can be accomplished by the addition of iodide ion to produce hypiodous acid (HIO), which reacts instantly with the indicator. Combined available chlorine is determined by difference.

In the free available chlorine test (FACTS), syringaldazine (formed by reacting syringaldehyde with hydrazine dihydrochloride in basic solution) is dissolved in 2-propanol. At a pH between 6 and 7, an aqueous solution of this reagent has an intense yellow color, but upon oxidation by FAC forms a violet, quinone-type product that has an absorption maximum at 530 nm (reaction [XX]). The pH range between 6 and 7 represents a compromise condition that produces rapid color development but slow color fading. Monochloramine (up to  $18 \text{ mg l}^{-1}$ ), dichloramine (up to  $10 \text{ mg l}^{-1}$ ), and oxidized forms of manganese (up to  $1 \text{ mg l}^{-1}$ ) do not interfere with the determination of FAC with syringaldazine. The primary difficulty with the FACTS method is the relative insolubility of the syringaldazine in 2-propanol or water, which causes problems in reagent preparation and color stability.

upon being oxidized, may provide increased sensitivity.

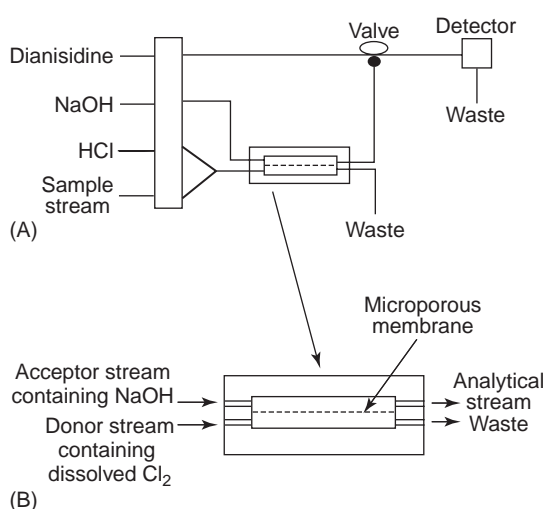

Bromine in aqueous solution has been determined fluorometrically with rhodamine B. The method can be adapted for the determination of dissolved chlorine by using the dissolved chlorine to form bromine in the presence of an excess of bromide ion.

Flame infrared emission (FIRE) spectrometry is a new technique that is useful in determining FAC in liquid bleach. In the FIRE method, solutions of sodium hypochlorite are acidified to produce aqueous  $\text{Cl}_2$  (reactions [I] and [II] and **Figure 1**). Dissolved  $\text{Cl}_2$  is liberated from solution in a purge tube and converted to vibrationally excited HCl molecules in a hydrogen-air flame. The intensity of the P-branch of the HCl stretching vibration at  $3.8 \mu\text{m}$  is monitored with a simple filter infrared photometer that employs a lead selenide detector.

**Other spectral methods** Red chemiluminescence is observed at 635 nm when hydrogen peroxide reacts with hypochlorite ion in alkaline solution. Unfortunately, the reaction is not sensitive enough for application to potable waters; however, substances such as luminol or lophine, which give chemiluminescence

By contrast with other methods for the determination of available chlorine, which are all based on oxidation-reduction chemistry and subject to potential interference from other oxidants present in the sample, FIRE actually measures a signal that is solely related to the amount of dissolved  $\text{Cl}_2$ .

**Figure 5** (A) Flow-injection assembly. (B) Detail of gas diffusion unit.

The sample is purged within seconds following addition of acid, and is not affected by the presence of chlorinated compounds that hydrolyze slowly in acid solution. A flow injection procedure has recently been developed that makes use of a continuous purge cell.

**Flow-injection methods** Flow-injection techniques have been developed and studied for the determination of free chlorine in industrial formulations and water samples. Figure 5 shows a schematic diagram of a flow-injection analysis (FIA) assembly that employs a gas-permeable membrane (0.5  $\mu\text{m}$  Fluoropore, Millipore) as a gas diffusion unit to separate dissolved chlorine from other potential matrix interferences.

With this apparatus, the sample (donor stream) is first mixed with hydrochloric acid to produce dissolved chlorine gas,

which subsequently diffuses across the gas-permeable membrane. Upon diffusing across the membrane, the  $\text{Cl}_2$  is converted back to hypochlorite ion by mixing with a NaOH acceptor stream,

Use of a basic acceptor stream facilitates transport of  $\text{Cl}_2$  across the membrane while, at the same time, permits preconcentration of the sample by stopping the flow of NaOH solution for a period of time. Following the preconcentration period, the flow of the acceptor stream is resumed and the sample is then mixed with *o*-dianisidine (4), producing a colored product that can be monitored at 445 nm. With a preconcentration period of a minute, limits of detection for chlorine

on the order of  $0.04 \text{ mg l}^{-1}$  can be achieved:

Gas diffusion FIA has also been used for the online determination of chlorine dioxide in potable water. In this example, chlorophenol red was used as the chromogenic reagent and a detection limit of  $0.02 \text{ mg l}^{-1}$  was achieved.

**Chromatographic methods** Chlorine dioxide is being used with increasing frequency in kraft mills and for water treatment because it does not form potentially carcinogenic THMs the way chlorine does. Since iodometric methods for the determination of chlorine dioxide are questionable, they should be avoided. While chlorine dioxide can be determined by amperometric titration and FIA with absorption spectrophotometric detection, chromatographic methods are becoming increasingly popular. Both high-performance liquid chromatography and ion chromatography (IC) have been used to determine inorganic chlorine species in aqueous samples. Since chlorine dioxide itself is not ionized in solution, it must be converted to  $\text{ClO}_2^-$  for IC analysis. To accomplish this conversion, samples are prepared in a basic solution containing hydrogen peroxide,

The  $\text{ClO}_2$  present is determined by difference between the chlorite found in a treated sample and that found in a separate aliquot that has not been dissolved in basic hydrogen peroxide.

Chlorine dioxide and hypochlorite have also been determined simultaneously in aqueous samples by high-performance liquid chromatography. The analytes are first separated on an anion-exchange column. After separation, a postcolumn reaction with 4-aminoantipyrine (5), and phenol is carried out, forming a chromogenic substance that absorbs at 503 nm through an oxidation-condensation reaction.

### Determination of Other Bleaching Agents and Disinfectants

**Oxidizing agents** Other oxidizing agents like peroxides and ozone are typically determined using variations of the methods used to determine FAC in solution. For example, peroxides may be determined by iodometric titration, by chemiluminescence, or by means of a colorimetric method based on syringaldazine.

Determination of ozone in aqueous solution is perhaps the most problematic for a variety of reasons: (1) ozone is unstable; (2) ozone is volatile and easily lost from solution; and (3) ozone reacts with many organic compounds to form products such as ozonides and hydrogen peroxide that are also good oxidants. Careful study of the use of iodometric methods for the determination of ozone in aqueous solution has revealed that the stoichiometric ratio of ozone reacted with iodine produced in the reaction varies from 0.65 to 1.5, depending on pH, buffer composition and concentration, iodide ion concentration, and other reaction conditions. As a result, iodometric methods are not recommended. Ozone can be determined iodimetrically by addition of an excess of a standard solution of As(III), followed by titration of the excess As(III) with a standard solution of iodine to a starch endpoint. Methods using DPD, syringaldazine, and amperometric titrations have also been developed.

In comparison to standard procedures involving iodide/iodine, colorimetric determination of ozone with indigo trisulfonate (**6**) has fewer interferences. In this procedure, indigo trisulfonate is oxidized by ozone to a leuco (colorless) form, and the decrease in absorbance is monitored at 591 nm. Ozone decomposition products and ozonolysis products formed from organic compounds do not interfere. Moreover, chlorite ( $\text{ClO}_2^-$ ), chlorate ( $\text{ClO}_3^-$ ), perchlorate ( $\text{ClO}_4^-$ ), and hydrogen peroxide do not decolorize the indigo reagent.

**Reducing agents** Methods for the determination of dissolved sulfite and dithionite generally involve reaction with oxidants. For example, aqueous solutions of sulfite can be determined by iodometric

titration to a blue, starch endpoint (reaction [XXV]):

Hydrogen sulfite can be determined in the presence of sulfite by oxidation with hydrogen peroxide to form hydrogen sulfate and sulfate (reactions [XXVI] and [XXVII])

followed by titration of the acidic hydrogensulfate ion with sodium hydroxide.

Aqueous solutions of dithionite ion can also be determined by iodometric titration to a blue starch endpoint (reaction [XXVIII]):

Dithionite solutions can be determined without interference from sulfite by the addition of formaldehyde. Formaldehyde reacts with sulfite ion to form an adduct that is not oxidized by iodine. Spectrophotometric methods for dithionite solutions are based on the reductive bleaching of dyes.

### Sampling

Aqueous solutions of chlorine are not stable and decrease in strength with time. Exposure to strong light accelerates the decomposition. Strong agitation should be avoided to prevent loss of chlorine gas by volatilization. Samples should be analyzed as soon as possible after collection and not stored. Most analytical methods require 100–200 ml of sample.

Because of the relative instability of chlorinated water samples, determination in the field is often required. Colorimetric test kits are available commercially for this purpose.

### Precautions in Handling

Bleaching agents and disinfectants are all strong oxidants that in concentrated form can react explosively with reductants, including organic matter. Disinfectants are effective because they are toxic to microorganisms, and in sufficient concentration will produce adverse health effects in humans. Chlorine gas, which is commercially available in steel cylinders as a gas over liquid, is a powerful irritant that can cause fatal pulmonary edema. Inadvertent addition of acid to liquid bleach ( $\text{NaOCl}$ ) causes the release of poisonous  $\text{Cl}_2$ . While chlorine dioxide dissolved in water is stable (if kept cool and away from light), the gas will detonate at pressures above

300 Torr. To avoid formation of explosive concentrations of  $\text{ClO}_2$  above the solution, the concentration of chlorine dioxide must be kept below 5 g  $\text{ClO}_2$  per liter of  $\text{H}_2\text{O}$ . Concentrated solutions of hydrogen peroxide also react explosively with organic matter.

Preparation of standard solutions of iodine and the amperometric determination of chlorine in water samples make use of arsenic trioxide ( $\text{As}_2\text{O}_3$ ) or phenylarsine oxide ( $\text{C}_6\text{H}_5\text{AsO}$ ), respectively, as reagents. These titrations generate toxic waste that must be disposed of in an environmentally safe manner. The cost of collecting and disposing of these reagents must be included in the cost of performing such determinations. Crystal violet is a suspected carcinogen and solutions formed from the leuco crystal violet method should also be treated as toxic waste.

## Introduction

Blood consists of a complex mixture of molecular and cellular components, some of which have yet to be identified. Quantitative and qualitative measurements in blood are indispensable for medical practice and biological investigation, but interpretation of the measurements requires knowledge not only of the analytical methods themselves, but of a variety of

other factors, some physiological and some artifactual, that can influence the results.

Measurements are made in blood for a variety of reasons, most commonly for diagnostic purposes and to assess the health status of the patient. The interpretation of such measurements requires the recognition of when the concentration of a particular component is in the abnormal reference range, which requires the knowledge of the normal reference range. This, of course, assumes that the normal concentration range is known. The normal concentration range is perhaps best established by measuring the component of interest in the general (i.e., free-living) population. This establishes the prevailing concentration range for the target population and can be considered as a first step in recognizing

abnormal values. In the absence of any additional information, the normal range is generally and somewhat arbitrarily defined as values that fall between the 5th and 95th percentiles of the prevailing distribution for components that are normally distributed in the population; values that fall outside this range are considered to be sufficiently unlikely that they can be considered abnormal. The prevailing concentration, however, may not always be the 'healthy' concentration. For example, the 95th percentile for serum cholesterol concentration in the USA is  $\sim 300 \text{ mg dl}^{-1}$ , but it is now well recognized that cholesterol concentrations exceeding  $200 \text{ mg dl}^{-1}$  in adults increase the risk for development of coronary artery disease. Thus, it should be recognized that the 'normal reference range' is not necessarily synonymous with 'healthy reference range'.

The second step in recognizing abnormal, or more properly, undesirable, levels of a particular component is to establish the relationship between its concentration and some manifestation of disease or risk for disease. Such relationships can be considerably more difficult to determine than ranges, because it is necessary to establish the relationship between concentration and disease or risk for disease without regard to arbitrarily defined limits, and ultimately, to establish in certain disorders whether the link between concentration and disease may be causal.

In many cases, blood analysis requires the qualitative determination of whether a particular component is present at all, for example, when assessing the presence of an antibody to establish whether the patient has been exposed to a particular pathogen. Finally, measurements in blood are also made in metabolic studies designed to elucidate normal metabolic pathways, test the safety and efficacy of medications, and determine the concentrations of various substances under defined metabolic conditions. Regardless of where or why such measurements are made, the ultimate aim of the laboratory is to provide accurate and precise measurements in individual specimens. In practice, this ideal can only be approximated. The extent to which it can be obtained depends on a number of factors including the nature of the methods employed, the availability of reference materials with which methodological error can be judged, and the circumstances under which samples are collected and handled before analysis (preanalytical factors). These factors can vary widely and can have serious medical, scientific, and economic consequences if their influence is not recognized. This article discusses some of the general principles that apply regardless of what is being measured. Specific details such as the sampling conditions, analytical methods, and quality control

procedures that apply to individual analytes are discussed in the entries dealing with particular measurements.

## Blood Composition

Blood is a complex non-Newtonian fluid that consists of several kinds of cells carried through the circulation in an isotonic aqueous medium, the plasma. Plasma contains a large number of proteins, salts, lipids, and various other nutrients and components. The cellular components normally account for  $\sim 45\%$  of the total blood volume. They include erythrocytes, leukocytes, and platelets. Erythrocytes constitute most of the total cell volume;  $\sim 1\%$  is accounted for by leukocytes, which include several types of cells. The major blood cell types and their concentrations are shown in **Table 1**. About 52% of total blood volume is water and the remaining 3% is contributed by dissolved solids, including protein and nonprotein components. The normal pH of plasma is  $\sim 7.4$ .

On average, the total protein concentration of the plasma, exclusive of the cellular elements, is  $\sim 78 \text{ g l}^{-1}$ . Approximately 58% of the plasma protein is albumin, and another 15% is IgG. The plasma lipoproteins include very-low-density lipoprotein, low-density lipoprotein (LDL), and high-density lipoprotein (HDL), which carry essentially all of the circulating lipids. Collectively they account for  $\sim 8\%$  of the total circulating plasma protein. Most plasma proteins are negatively charged at physiological pH. The major plasma proteins are shown in **Table 2**.

**Table 1** Normal cell composition of blood

Cell type	Mean cell concentration <sup>a</sup> (cells per liter)
Erythrocytes	
Males	$5.2 \times 10^{12}$
Females	$4.6 \times 10^{12}$
Leukocytes <sup>b</sup>	$7.4 \times 10^9$
Neutrophils (total)	$4.4 \times 10^9$
Band neutrophils	$0.2 \times 10^9$
Segmented neutrophils	$4.2 \times 10^9$
Eosinophils	$0.2 \times 10^9$
Basophils	$0.04 \times 10^9$
Lymphocytes	$2.5 \times 10^9$
Monocytes	$0.3 \times 10^9$
Platelets	$310 \times 10^9$

<sup>a</sup>Data from Nelson DA and Morris MW (1991) Basic examination of blood. In: Henry JB (ed.) *Clinical Diagnosis and Management by Laboratory Methods*, 18th edn., pp. 553–603. Philadelphia: WB Saunders.

<sup>b</sup>Leukocytes include a number of cell types broadly characterized as neutrophils, band cells, lymphocytes, monocytes, eosinophils, and basophils.

**Table 2** Major plasma proteins

Protein	Concentration <sup>a</sup> (g l <sup>-1</sup> )
Albumin	45.0
IgG	11.0
$\beta$ -Lipoprotein (low-density lipoprotein)	5.0
$\alpha_1$ -Antitrypsin	3.0
Transferrin	3.0
A <sub>2</sub> -Macroglobulin	2.5
Fibrinogen	2.5
IgA	2.0
Haptoglobin	1.7
IgM	1.1
C3	1.0
Prealbumin	0.3
IgD	0.3
TgE	0.003

<sup>a</sup> Data from McPherson RA (1991) Specific proteins. In: Henry JB (ed.) *Clinical Diagnosis and Management by Laboratory Methods*, 18th edn., pp. 215–228. Philadelphia: WB Saunders.

In addition to proteins, the plasma contains a large number of other anions, the most predominant of which are chloride and hydrogencarbonate. Smaller amounts of phosphate, sulfate, and organic acids are also present. Plasma also contains a number of cations, most predominantly sodium, and lesser quantities of potassium, calcium, and magnesium. The total cation concentration is  $\sim 150 \text{ mmol l}^{-1}$ , and since electrical neutrality must be maintained, the total anion concentration is similar. However, when subtracting the concentration of the major anions ( $\text{Cl}^-$  and  $\text{HCO}_3^-$ ) from the major cations ( $\text{Na}^+$  and  $\text{K}^+$ ), the result is not zero, but usually between 10 and  $20 \text{ mmol l}^{-1}$ . This is known as the ‘anion gap’ and represents the unmeasured anions (e.g.,  $\text{PO}_4^{2-}$ ,  $\text{SO}_4^{2-}$ , and organic acids).

These components represent diverse functions including the transport of nutrients to the tissues and of waste products from the tissues to be reused or excreted, the maintenance of blood pH within physiological limits and the movement of effectors such as hormones from their sites of synthesis to their respective target tissues. Some of these components are actually dissolved in the plasma, and some, such as lipids that are insoluble in an aqueous environment, are transported in the form of lipid–protein complexes, the lipoproteins. In other cases, for example, calcium and hormones, some may exist free in the plasma, and some may be protein bound. In these cases, only the free fraction is biologically active.

## Blood Sampling

When making a measurement in a blood sample obtained from a patient on a given occasion, the

measurement should accurately represent the concentration of the measured component at the time the sample is obtained. The accuracy of the measurement can be affected by artifacts arising from improper blood collection techniques (such as posture, hemoconcentration due to prolonged venous occlusion, and destruction of cells (hemolysis)), the conditions under which serum or plasma is prepared, stored, and transported to the laboratory, and from analytical errors inherent in making the measurement itself. Reliable measurements are more likely to be obtained when the samples have been collected atraumatically and handled properly prior to the analysis. While an unusual value in an individual patient may be commonly ascribed to ‘laboratory error’, in many cases blood samples are drawn in locations remote from the laboratory and under conditions over which the laboratory has no control. The sample may suffer changes such that the measured concentration no longer represents the concentration of the component at the time the patient was sampled. The conditions for blood sampling, preparation, and storage vary according to the measurements required, and it is not possible here to discuss the requirement for individual tests. Nonetheless, certain general principles can be outlined that will apply in most circumstances, although procedures may have to be modified for particular tests.

## Serum and Plasma

Most clinical tests are performed in venous samples of serum or plasma. Serum is prepared by allowing the blood specimen to coagulate. This is best accomplished by collecting the specimen into a glass tube and allowing it to stand at room temperature for at least 45 min. The clot is then sedimented by centrifuging at  $\sim 2500g$  (relative centrifugal force ( $g$ ) =  $1.118 \times 10^{-5} \times r \times n^2$  ( $r$  is the radius in centimeters from center of rotation to the bottom of the tube in the rotor bucket,  $n$  the rotor speed in revolutions per minute (rpm))) for 15–30 min, and the supernatant serum is removed to a clean storage container. Serum separator tubes contain a gel, which facilitates the separation of the serum from the cellular components based on the difference in density. Using such tubes for blood collection obviates the need to transfer the serum to a separate container as the gel forms an effective barrier. The serum contains all of the original plasma components except the cellular elements and protein components that constitute the clot. The concentrations of serum components are taken to represent their concentrations in the circulation.

For some components, it is necessary to use whole blood or plasma. This requires the addition of an anticoagulant to the blood sample as it is being collected or immediately thereafter. Some commonly used anticoagulants include heparin, sodium, potassium, or lithium ethylenediaminetetraacetic acid (EDTA), citrate, and oxalate salts. EDTA, oxalate, and citrate prevent clotting by complexing  $\text{Ca}^{2+}$ , which is required for coagulation; heparin interferes with the formation of fibrin. The particular anticoagulant used varies according to the test. Some anticoagulants, such as citrate and oxalate, can, in the concentrations used to prevent clotting, change the osmolarity of the plasma and induce a shift of water from red cells to the plasma. This dilutes the plasma and can reduce the concentrations of nondiffusible plasma components such as proteins and lipoproteins by 10% or more. Heparin, because it is used in much lower concentrations to prevent coagulation, exerts almost no osmotic effect, whereas EDTA can cause a less severe, but still noticeable (3–5%) dilution. Depending on the component being measured and the anticoagulant used, it may be necessary when interpreting the measurements to account for these effects, particularly for some components that are usually measured either in serum or plasma.

When plasma is to be used, the anticoagulant must be completely mixed with the atraumatically obtained blood sample. This can be accomplished using a blood mixing apparatus, or by gently inverting the collection tube 5–10 times. The cellular components are sedimented by centrifuging at 4°C for 15–30 min at ~2500g. Under these conditions, virtually all of the cellular elements are removed; the few remaining platelets can be removed by centrifuging the plasma again, but in most cases this is not necessary. The plasma is removed and stored in a clean storage container. The containers should be sealed to prevent evaporation and contamination during storage and transport to the laboratory.

Regardless of whether serum or plasma is used, and with some exceptions, the cellular components should be removed as soon as possible, generally within 1 h. In most cases, the serum or plasma should be stored at 2–4°C before analysis. The maximum period of storage varies with the analyte, but in most cases, periods of up to several days are acceptable. For longer periods, samples can generally be stored at –20°C for moderate periods (up to several months), or at temperatures of –70°C to –80°C or lower for longer periods (years). Self-defrosting freezers should not be used because their temperature can fluctuate between ~–2°C and ~–20°C during the daily defrost cycle. Such wide temperature variations can reduce sample stability. In all cases, the

samples should be handled as aseptically as possible to prevent bacterial growth. Samples drawn in one location are frequently shipped to the laboratory at room temperature as a matter of convenience. Depending on where and how the sample is shipped, however, the climate at the time of shipment, and other factors such as ‘room temperature’ can vary considerably and may have deleterious effects on the sample. For some components, room temperature shipment is not acceptable because of compositional changes that may occur due to enzymatic or other alterations. In such circumstances samples are normally shipped at 2–4°C or frozen and shipped on dry ice, which maintains a temperature of ~–40°C.

### Posture

The patient is usually in the sitting position when blood is drawn. In some instances, for example, when the patient is confined to bed, it may be necessary to sample the patient in the supine position. The concentrations of some components vary in response to postural change, however, and if it is necessary to use the supine position, the same position should be used each time that patient is sampled. Posture-related changes in concentration occur in part because of the redistribution of water between the blood and the tissues. When a standing subject sits or reclines, water tends to move from the tissues to the circulation and dilutes large components such as proteins and lipoproteins, or small molecules that are associated with the macromolecules, which are not as readily diffusible as water itself. Other factors not presently understood can also contribute to these changes. The magnitude of postural effects thus varies depending on the component. The changes occur rapidly, are maximal within 20–40 mm, and are reversible upon returning to the standing position. For example, plasma triglycerides, which are associated with lipoproteins, can decrease by ~20% when a standing subject reclines. Plasma cholesterol, also carried on lipoproteins, decreases by ~10% under these conditions. The changes are about half as great when a standing subject sits. On the other hand, the concentration changes for components such as sodium, potassium, creatinine, or glucose are insignificant. Table 3 illustrates posture-related changes in the concentrations of some commonly measured blood components. As can be seen, the changes range from insignificant to ~20%.

### Venous versus Capillary Blood

Venous blood is most commonly used, but capillary samples can also be used, depending on the analyte

**Table 3** Postural changes in blood component concentrations

Component	Percent change
<i>Supine compared to standing</i>	
Cholesterol <sup>a</sup>	-10
Triglycerides <sup>a</sup>	-18

NS, not significant.

and method to be used for the measurement. Capillary blood is usually obtained by fingerstick, heel-stick (commonly used for infants), or from an earlobe. It more closely resembles arterial than venous blood, but in many instances values obtained from capillary and venous blood are similar. It is important to realize, however, that the concentrations of some analytes will more closely resemble those found in whole blood than in venous serum or plasma (capillary blood glucose concentration for example may be 10-15% lower when measured in a point of care instrument compared to plasma or serum concentration).

Venous samples are usually taken from an antecubital vein. A tourniquet is usually used for this procedure, but prolonged application of the tourniquet can artifactually increase the concentrations of non-diffusible blood components. For lipids, these effects are observed when the tourniquet is applied for longer than ~2 min. Capillary samples are more easily obtained than venous samples, and are

convenient when the analyses must be done rapidly, require only a small amount of specimen, and when methods are available to perform the measurements at the sampling site rather than in the laboratory. Measurements in capillary samples tend to be more variable than in venous samples, however. The reasons for this are not completely understood, but factors such as the possible contamination of blood with tissue fluid during sample collection, the puncture procedure used and variations in the ease with which blood flows from the puncture site, and the characteristics of the analytical methods themselves undoubtedly play a role.

## Normal Physiological Variation

The concentration of a particular component is generally not fixed, but fluctuates around a person's homeostatic set point during the normal course of daily activity. Measurements made in a sample obtained from a given individual on one occasion will usually differ from the values measured in samples obtained on other occasions. These variations occur even though the individual may be in a steady state, i.e., consuming a usual diet, not ill, not gaining or losing weight, or changing medications or dosages, and who is maintaining normal patterns of activity. Such normal variation can occur as a consequence of food intake, postural change, routine daily activity, diurnal variations, and other factors. Since the concentrations of blood components vary somewhat in individuals over time, a measurement made on a single occasion may not reflect the average or usual concentration of a particular component in the individual, even in the absence of analytical error. Physiological variations can usually be reduced to some extent, but they cannot be eliminated entirely. Fasting samples can be used for components whose concentrations may change postprandially. Blood drawing can be standardized to a particular posture, and the patient can be requested to remain in this posture for a specified period before blood is drawn. Even under such conditions, however, there will be concentration differences among serial specimens, and the results in several samples may have to be averaged to determine the patient's usual concentration. This is because the mean of two or more measurements varies less than the individual measurements themselves. The number of serial specimens required depends on a number of factors including the purpose of the measurement (e.g., whether it will be used as a screening tool; for diagnosis or follow-up; for a population survey), the extent to which the concentration is expected to vary normally, the

possible medical consequences or medical decisions that may arise from an unusually high or low value in a particular patient, and the reproducibility of the analytical procedure used for the measurement.

The physiological variation that occurs in a particular individual when in the steady state can be assessed using two or more samples drawn on different occasions. The magnitude of the variations observed in such measurements depends on two factors, normal physiological or biological fluctuations and the reproducibility of the measurement method itself. The latter is referred to as 'analytical variation' and is generally determined by the laboratory through the repetitive measurement of one or more serum pools of known concentration. Such pools are analyzed with every batch of patient samples and are used to monitor the accuracy and reproducibility of the measurements. The mean (and standard deviation, SD) measured value for a particular pool is calculated and the reproducibility of the measurement is usually expressed as a percentage in terms of the coefficient of analytical variation ( $CV_A$ ):

$$CV_A = \frac{SD}{Mean} \times 100$$

Physiological variation is established as follows. The mean (and SD) for measurements in serial samples from the same individual is calculated. The variation can also be expressed in terms of a coefficient of total variation,  $CV_T$ .  $CV_T$  includes the contributions of both physiological and analytical variations. Physiological variation ( $CV_P$ ) is estimated by adjusting the coefficient of total variation for the contribution of analytical variation. If analytical variation is small compared to physiological variation,  $CV_T$  will

approximate  $CV_P$ . The following formula is used to assess whether two serial samples, taken from the same individual, are significantly different:

$$SD (\%) = 2.8 \times \sqrt{CV_A^2 + CV_P^2}$$

If the two results differ by more than the significant difference there is a greater than 95% probability that this difference is not due to the analytical or physiological variation. Knowledge of the analytical and physiological variations also allows the calculation of the number of specimens required to ensure that the mean result is within 5% of the individual's homeostatic set point. This is given by the following

**Table 5**  $CV_T$  for mean total cholesterol concentrations in serial samples from individuals

Number of specimens <sup>a</sup>	$CV_A$ (%)	$CV_T^b$ (%)	
		$CV_P = 5.0\%$	$CV_P = 9.0\%$
1	2.0	5.4	9.2
2		4.1	6.7
3		3.5	5.6
4		3.2	4.9
5		3.0	4.5
1	5.0	7.1	10.3
2		6.1	8.1
3		5.8	7.2
4		5.6	6.7
5		5.5	6.2

<sup>a</sup>Specimens should be taken at least 12 weeks apart.

Glucose <sup>b</sup>	6			9

<sup>a</sup>Data from Kafonek SD, Derby CA, and Bachorik PS (1992) Biological variability of lipoproteins and apolipoproteins in patients referred to a lipid clinic. *Clinical Chemistry* 38: 864–872.

<sup>b</sup>Data from Harris EK, Kanofsky P, Shakarji G, and Cottlove E (1970) Biological and analytical variation in long-term studies of serum constituents in normal subjects. II. Estimating biological components of variation. *Clinical Chemistry* 16: 1022–1027.

<sup>c</sup>Bachorik *et al.*

formula:

$$n = z^2 \times \left( \frac{CV_A^2 + CV_P^2}{d^2} \right)$$

where  $n$  is the number of specimens,  $z$  is the number of standard deviations required for a stated probability under the normal curve (for  $p < 0.05$ ,  $z = 1.96$ ), and  $d$  is the desired percentage closeness to the homeostatic setpoint.

The magnitude of intraindividual variation differs in different individuals. An example of this is provided in Table 4, which lists the average and selected percentiles for  $CV_P$  for several plasma components. As can be seen, the physiological fluctuations for the components shown vary from 3% to ~20% on average, but can be considerably higher in some individuals.

The  $CV_T$  observed for the mean level in one or more serial specimens from the same individual depends on the physiological variation in that individual, the number of serial specimens collected, and the  $CV_A$  for the measurement method itself. This is illustrated in Table 5 for total cholesterol. The table shows the expected  $CV_T$  for the mean of up to five serial specimens for individuals with  $CV_P$ s at the 50th and 75th percentiles when the measurements are performed with  $CV_A$ s of 2.0% or 5.0%. The

lower value reflects reasonably well the  $CV_A$ s that would occur in a well-controlled clinical laboratory using modern automated equipment. The higher  $CV_A$  is in the range observed with many physicians' desktop analyzers. For an individual with a median  $CV_P$  (5%) whose samples were analyzed with a  $CV_A$  of 2%, the coefficient of total variation would be below 5% if using two serial specimens. To achieve a  $CV_T$  below 5% would require at least four serial specimens if the subject had a  $CV_P$  at the 75th percentile (9%). Even five serial samples would not be sufficient to achieve a  $CV_T$  of less than 5% if the  $CV_A$  was 5%. Because of the interplay of these factors, it is necessary.

## BUFFER SOLUTIONS

**A Hulanicki and S Głab**, University of Warsaw, Warsaw, Poland

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

A buffer solution, or simply a buffer, is a chemical system added to keep constant, or at least minimize, the variation of a particular property. Initially, buffer solutions were used to stabilize the pH of the reaction medium. Subsequently, metal buffers were introduced to keep the free metal ion concentration constant. Redox buffers are used to stabilize the

redox potential. The term buffer is also used in other situations encountered in analytical chemistry. In this article, the simple theory of the buffering mechanism is given along with some examples of different buffers used in the laboratory practice.

### Various Concepts of Buffers

A buffer solution is a system that has the property of being able to eliminate or diminish the influence of external conditions on a chemical system. This term is most commonly used for acid–base systems, and they are named pH buffers. These buffers are added to solutions to prevent a change in their pH value

occurring on addition of acidic or basic solutions, when the solution is diluted with a solvent, or when in a reaction an undesirable pH is expected to occur. The discussion of such buffers will occupy the main part of this article.

The term buffer is also occasionally applied to other systems. Metal buffers are used when it is necessary to maintain free metal concentration at a constant level. Redox buffers are designed to keep the redox potential of a solution constant. They contain a mixture of oxidized and reduced substances. In measurements by ion-selective electrodes, the term ionic strength buffer is used to denote a solution that is added to keep the ionic strength, and in consequence the activity coefficients, of a given solution constant. Such systems may be called buffers only when they are able to keep the buffered parameter constant and when in the absence of the buffer the given parameter alters significantly. For example, the total ionic strength adjustment buffer, used in measurements with ion-selective electrodes, exhibits a buffering capacity only because it has a relatively high content of the ionic-strength-adjusting electrolyte. However, at the same time they may play another role in the measurements, e.g., complexing some interferents.

In another field, the term buffer (but not buffer solution) is used for substances that are added to the samples introduced to the excitation source in atomic spectroscopy to prevent any change in the excitation conditions due to accompanying elements. Mainly this refers to maintaining constant temperature or electron density.

## Theory of pH Buffers

A pH buffer owes its buffering action to the fact that after the addition of hydrogen ions or hydroxyl ions the position of the equilibrium of weakly dissociated electrolytes (acids or bases) is shifted in such a way that the added ions are consumed. This is mainly applicable to aqueous solutions, but the same concept is valid for any amphoteric solvent.

The weak acid, HA, reacts in solution according to eqn [1]:

This equilibrium is characterized quantitatively by the acid dissociation constant given in eqn [2]:

$$K_a = [\text{H}_3\text{O}^+][\text{A}^-]/[\text{HA}] \quad [2]$$

Here, the expressions in square brackets denote molar concentrations.  $K_a$  is a concentration constant,

but more correct would be to express it in terms of activity. In this case, the constant is termed a thermodynamic constant. Depending upon which convention is used, the appropriate constant must be used.

From eqn [2], the hydrogen ion concentration can be calculated as shown in eqn [3]:

$$\begin{aligned} [\text{H}_3\text{O}^+] &= K_a[\text{HA}]/[\text{A}^-] \quad \text{or} \\ \text{pH} &= \log([\text{A}^-]/[\text{HA}]) + \text{p}K_a \end{aligned} \quad [3]$$

This equation shows that in order to maintain the pH value constant the logarithmic term containing the concentration ratio should be allowed to vary as little as possible. When the solution contains a mixture of the acid, HA (Brønsted acid), and the weak base,  $\text{A}^-$  (Brønsted base), the addition of a base results in further dissociation of the acid according to eqn [4]:

The concentration of free hydrogen ions therefore decreases. In the reverse situation, when hydrogen ions are added or produced they combine with the base according to eqn [5]:

When the buffer solution is diluted the ratio of concentrations does not change at all and the pH value, in principle, should remain constant.

The buffering property of a solution is preserved as long as the concentrations of the components in the buffer are greater than the amounts of added hydroxyl ions (base) or hydrogen ions (acid). If this is not the case then the buffer solution does not function according to expectations. It is then said that the buffer capacity is too small.

The buffer capacity depends on the absolute concentrations of the two components: buffer capacity toward addition of acid depends on the concentration of the base, while buffer capacity toward addition of base depends on the concentration of the acid. The definition of the buffer capacity can be expressed as

$$\beta = dC/d\text{pH} \quad [6]$$

Its exact value can be calculated from a much more complicated expression that takes into account the presence of several buffering systems:

$$\beta = \left( \frac{K_w}{[\text{H}_3\text{O}^+]} + [\text{H}_3\text{O}^+] + \sum \frac{C_i K_a [\text{H}_3\text{O}^+]}{(K_a + [\text{H}_3\text{O}^+])^2} \right) \quad [7]$$

In this equation,  $K_a$  refers to the acid dissociation constant (reciprocal of the protonation constant) of

**Figure 1** The buffer capacity of a mixture of two systems,  $0.10 \text{ mol l}^{-1}$  acetic acid and  $0.10 \text{ mol l}^{-1}$  ammonia, as a function of pH.

the buffer component with total concentration,  $C_i$ , and  $K_w$  the autoprotolysis constant of water. The  $\Sigma$  symbol indicates that the equation can take into account several buffering systems present in the solution. The first term in the brackets is equivalent to the concentration of the base ( $\text{OH}^-$ ), which in combination with water present as solvent also forms a buffer system. Therefore, it is often said that the solution of a strong base has buffering properties. The same can be said about the second term, which refers to the acid ( $\text{H}_3\text{O}^+$ ) and also buffers in the acidic range (Figure 1).

## Preparation of Buffer Solutions

In principle, any acid–base system can be used to prepare a buffer solution. In practice, several conditions must be fulfilled. First, the logarithm of the protonation constant should not differ by more than one unit from the required pH value of the buffer. This will provide sufficient buffer capacity for the buffer solution. The other conditions are that the components in the buffer must be available at high purity grade or can be easily purified; they must be stable in time in both pure state and in solution; and they should not undergo reactions such as oxidation by air oxygen. In a number of buffer solutions, in particular when they contain organic species, mold growth may occur in the pH range 3–11. This obviously disqualifies the use of the buffer. To prevent this, a preservative (e.g., thymol) may be added.

A standard set of such acid–base systems has been recommended for establishing the pH scale, i.e., for calibrating pH meters. The pH value of standard buffer solution corresponds to the activity of the hydrogen ion. The pH value varies with temperature as

the activity coefficients and the dissociation constants are temperature dependent. Generally, the  $\text{dpH/dT}$  coefficient is negative, which means that with increasing temperature the pH value decreases. Among the standard buffers the change is largest for the carbonate buffer and corresponds to  $0.0096 \text{ pH unit per degree Celsius}$ .

When pH buffers are used in analytical procedures to provide approximately constant pH value, they are prepared by mixing the acid with the base in given proportions, by adding a strong base (e.g., NaOH, KOH) to the solution of a weak acid until the desired pH value is attained, or by adding a strong acid (e.g., HCl,  $\text{HNO}_3$ ) to a weak base solution. Acetate, phosphate, or ammonia buffers are commonly used in analytical practice. It is important to check that the buffer components will not react in an uncontrolled way with the substrates or products of the reaction being studied or applied analytically. In this respect, phosphate buffers are less convenient as they may react with many of the metal ions studied.

The buffers used in biochemical studies should have a pH value not far from neutral and should not complex or form precipitates with calcium. Among them are the so-called ‘Good buffers’ that contain zwitterionic amino acids such as *N*-substituted taurines or glycines. Examples of such buffers are Hepes (4-(2-hydroxyethyl)piperazine-1-ethanesulfonic acid), Tris (tris(hydroxymethyl) aminomethane), and Tricine (*N*-[Tris(hydroxymethyl)methyl]glycine):

For special applications additional requirements are imposed on buffer solutions. For spectrophotometry, the buffer used should not absorb radiation in the region where the species that are being studied exhibit absorption. Buffer solutions find important application in electrophoretic separations of biomolecules in the electric field, which, depending on the pH value of the medium, acquire a positive or negative net charge. The components of the buffer have similar properties as the buffers used in biochemical investigation, but, in addition, have a polymerizable part, may be immobilized on a polymer matrix, forming a stable pH gradient. Buffers used in voltammetric studies should not undergo, in the used potential range, electrochemical reduction or oxidation. The buffers used in extraction, spectrophotometry, or voltammetry often possess complexing properties that may enhance the selectivity of

determination. For biochemical and medical applications, the buffers used should be isotonic with respect to the fluids under investigation. Such buffers usually contain a mixture of mono- and disodium hydrogenphosphate, the ionic strength being adjusted with sodium chloride.

For routine work commercially available mixtures are useful. These contain several components and the addition of specified amounts of a strong base is all that is required for the preparation of the buffer solution. Among these is Britton–Robinson buffer (Table 1), which contains acetic, phosphoric, and boric acids. Universal buffers for spectrophotometry may contain such components as chloroacetic, formic, acetic, phosphoric, succinic, citric, boric acids, tris(hydroxymethyl)aminomethane, and butylamine. These buffers are transparent at wavelengths at least down to 240 nm.

Many naturally occurring systems are able to maintain a constant pH value by making use of buffer systems. In blood the hydrogencarbonate and protein systems maintain a pH  $\sim 7.4$ . In open ocean water the pH is kept within the range 7.9–8.3 by a multicomponent buffer that includes aluminosilicates and carbonates.

The composition and pH values of a range of commonly used pH buffers, including Good buffers, is given in the appendix section of the encyclopedia.

## Metal Buffers

Metal buffers are solutions that contain a given concentration of free metal ions, usually very small, which is kept constant by the addition of a suitable ligand. The basic theory is similar to that for the pH buffers. If a metal ion, M, reacts with a ligand, L, according to the equation:

for which the equilibrium (stability) constant can be written as

$$\beta_r = [ML_r^{(m-nr)}] / [M^{m+}][L^{n-}]^r \quad [9]$$

then

$$pM = \log([L^{n-}] / [ML_r^{(m-nr)}]) + \log \beta_r \quad [10]$$

where  $m$  and  $n$  are charge numbers for M and L, respectively, and  $r$  is the stoichiometric coefficient for the M–L complex.

If the ligand is present in excess and the complexes are relatively strong, then the ratio  $[ML_r^{(m-nr)}] / [M^{m+}]$  is practically constant and pM, being the negative logarithm of metal ion concentration, is maintained at a constant level. These considerations

**Table 1** Composition of Britton Robinson buffers. To 100 ml of a solution containing  $0.04 \text{ mol l}^{-1}$  acetic acid,  $0.04 \text{ mol l}^{-1}$  phosphoric acid, and  $0.04 \text{ mol l}^{-1}$  boric acid, X ml of  $0.2 \text{ mol l}^{-1}$  sodium hydroxide solution is added to obtain the required pH at  $18^\circ\text{C}$

X	pH	X	pH	X	pH
0.0	1.81	35.0	5.02	70.0	9.15
2.5	1.89	37.5	5.33	72.5	9.37
5.0	1.98	40.0	5.72	75.0	9.62
7.5	2.09	42.5	6.09	77.5	9.91
10.0	2.21	45.0	6.37	80.0	10.38
12.5	2.36	47.5	6.59	82.5	10.88
15.0	2.56	50.0	6.80	85.0	11.20
17.5	2.87	52.5	7.00	87.5	11.40
20.0	3.29	55.0	7.24	90.0	11.58
22.5	3.78	57.5	7.54	92.5	11.70
25.0	4.10	60.0	7.96	95.0	11.82
27.5	4.35	62.5	8.36	97.5	11.92
30.0	4.56	65.0	8.69	100.0	11.98
32.5	4.78	67.5	8.95		

are true in the exceptional case where the ligand has no protolytic properties. Usually, the system shows strong pH dependence and an additional pH buffer is needed. When polyprotic species are used as ligands they may simultaneously act as pH buffers. The ligands used for metal ion buffers are strong chelating agents such as polyaminopolycarboxylic acids (e.g., nitrilotriacetic acid; ethylenediaminetetraacetic acid (EDTA)) and their salts, macrocyclic polyamines (e.g., 1,4,7,10-tetraazacyclododecane), or aliphatic polyamines (e.g., ethylene diamine). As an example, a solution containing  $1 \times 10^{-3} \text{ mol l}^{-1} \text{ Ca}^{2+}$  and  $5 \times 10^{-3} \text{ mol l}^{-1}$  nitrilotriacetic acid at pH 8.04 in the presence of  $0.1 \text{ mol l}^{-1} \text{ NaCl}$  acts as a calcium buffer (pCa buffer) for constant ionic strength. Such a buffer keeps the calcium ion concentration at the chosen pCa level in the range from four to seven.

There are two types of one-phase metal buffers: one containing the metal ion of interest and a complexing ligand, and the other containing, in addition, another metal ion, which is in excess compared to the two other components but is less strongly complexed by the ligand. The latter type of system is less influenced by pH changes of the solution. This is because the pH changes affect the stability of the second complex in the same way as that of the first metal ion. In the system containing  $10^{-3} \text{ mol l}^{-1} \text{ Pb}^{2+}$ ,  $0.1 \text{ mol l}^{-1} \text{ Mg}^{2+}$ , and  $10^{-2} \text{ mol l}^{-1}$  EDTA the value of pPb equals 11.25, 11.29, and 11.29 at pH 5.0, 7.0, and 9.0, respectively. However, dilution affects the pM values of these metal buffers.

Metal buffers are used for the calibration of ion-selective electrodes at low ion levels (below  $10^{-5} \text{ mol l}^{-1}$  where the preparation of standard

solutions by simple dilution may give rise to errors due to losses (adsorption, side reactions) or contamination. Another application is to provide a medium of fixed ion concentration for selective precipitations. An important application of metal buffers is for the investigation of biochemical reactions influenced by the ion concentration of a particular metal (e.g., calcium), as in the study of calcium-sensitive enzymes such as ATP phosphohydrolase.

## BUILDING MATERIALS

**L W Cheriton and J P Gupta**, Fosroc International Ltd., Birmingham, UK

© 2005, Elsevier Ltd. All Rights Reserved.

This article is reproduced from the previous edition, pp. 407–417, © 1995, Elsevier Ltd., with an updated Further Reading list supplied by the Editor.

An extremely wide range of materials can be used for building. These can be either natural or man-made. Natural materials include aggregates, bitumen, clays, rubber, stone, and wood; man-made materials include brick, inorganic cements, glass, plaster, metals and their alloys, synthetic polymers, and wood preservatives.

The purpose of analyzing any of these materials can vary from product failure, through quality control to product development. From an analytical point of view the materials are best classified as organic or inorganic. The inorganic group can be further subdivided into metallic and nonmetallic.

Modern instrumental analytical techniques are considered where appropriate, as they usually provide the most cost-effective, efficient, and most accurate results. Frequently British Standard (BS) and American Society for Testing and Materials (ASTM) methods are quoted where appropriate. Even though these methods can be quite similar, small differences in results can arise. It therefore

follows that if testing is required to a certain standard, then the actual standard must be used. At the time of writing, work is underway to incorporate many British Standards into European Standards (ENS). These have not been referred to at this time.

### Organic Materials

Two important organic materials used in the building industry are wood- and oil-based products.

#### Wood

Wood consists of 40–50% cellulose, 20–30% hemicelluloses, 21–23% lignin, 0.2–0.5% protein, and 1–5% mineral matter, which is left behind as ash when the wood is burned. Besides its straightforward use as timber, much wood is pulped for use in paper-making. Lignin is extracted in the process by either sulfonation or chlorination. Sulfonation produces lignosulfonates, which are widely used as dispersing agents, for example as chemical admixtures for concrete to disperse the cement particles (see the section on Cement and Concrete Admixtures, below).

Timber itself is usually treated with chemical preservatives (fungicides/biocides) to prevent attack by fungi or insects. Such materials include organotin salts, tri-*t*-butyltin (TBT), TBT oxide (TBTO), TBT

phosphate (TBTP), TBT naphthanate (TBTN); as well as 2-mercaptobenzothiazole (MBT), copper(II) oleate, organozinc and copper salts, pentachlorophenol (PCP), creosote, and phenyl mercury(II) acetate. These will require analysis, for example, in a survey to ascertain whether the timber used in a structure has been treated.

**Analysis** The chemical analysis of wood is carried out by ASTM (American Society for Testing and Materials) and TAPPI (Technical Association of the Pulp and Paper Industry) standards. These methods can be summarized as in Table 1 following milling to  $-40$  mesh ( $400\ \mu\text{m}$ ) and air drying.

Modern analytical such as infrared (IR) spectroscopy, liquid chromatography (LC), and gas-liquid chromatography (GLC) are in use for the identification of organic components, whilst the mineral constituents can be estimated by using X-ray fluorescence (XRF) spectrometry, X-ray diffraction (XRD), atomic absorption spectrometry (AAS), or inductively coupled plasma (ICP) atomic emission spectrometry (AES).

The above methods are also employed for the analysis of wood preservatives. The metallic component is determined by AAS or ICP-AES after oxidation of the organic matter in a mixture of concentrated sulfuric and perchloric acids. Nuclear magnetic resonance (NMR) spectroscopic techniques have also been mentioned in the literature for the identification of components from a complex formulated wood preservative.

## Oil

Oil is the principal raw material for the plastics industry and is used to produce a vast range of products used in the building industry.

**Polymers** Polymers in long chains are known as thermoplastic, e.g., polypropylene, which can be used for hot-water pipes.

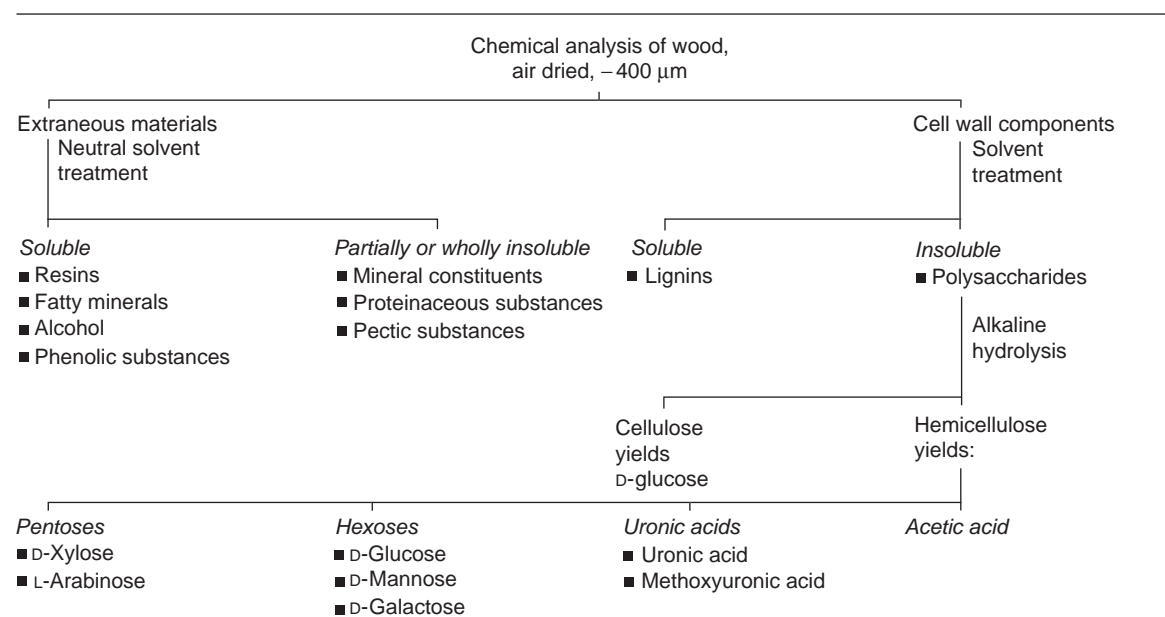

Cross-linked polymers are known as thermosetting. Polyesters have wide applications in building, e.g., in glass-reinforced plastic (GRP) and chemical anchoring.

Polymers in the form of spongy chains are known as elastomers. Polyurethane is an example of an elastomer. Elastomers are used to fill moving joints in construction, e.g., between concrete slabs on a road or runway.

Polymers are also used to form compounds that, when added to building materials, modify their properties. For example dibutylphthalate (DBP) is often used as a plasticizer to improve the flexibility of a plastic formulation.

Melamine formaldehyde sulfonate and naphthalene sulfonates are added to concrete to 'plasticize' the mix. A 'plasticizer' in concrete technology is a cement-dispersing agent. Other polymers can be added to cement mortars/concretes to improve flexibility and reduce permeability to water, e.g., styrene butadiene rubber (SBR) emulsions; to give air entrainment for freeze-thaw resistance, e.g., alkyl sulfonates; or to thixotropize a mix, e.g., polyacrylamide.

**Table 1** Analytical methods for wood

Polymers are also used extensively in the paint industry. The trend is away from solvent-based systems to the more environmentally friendly water-based emulsions.

It is important to be able to determine the small amounts of polymers present in concrete, for example, in the event of failure. This will be discussed further later.

**Analysis** The International Standards Organization (ISO) Technical Committee 61 on plastics has developed and promulgated more than 100 standards (ISO, Geneva, Switzerland), many of which describe test methods for the analysis and evaluation of plastic materials.

The development of instruments for the analysis and characterization of plastics has greatly facilitated the study of their composition, structure, molecular parameters, and performance. **Table 2** summarizes these methods and parameters for which they are suitable.

Paint is also analyzed using the methods given in **Table 2** as it is a mixture of polymers, pigments, extenders, carrier solvents, and additives. More appropriately, its testing almost always involves determining performance properties rather than chemical composition. For example, hiding power is not calculated from refractive index and particle size measurements, but by measuring and comparing the reflectance of the paint over black and white substrates.

**Table 2** Polymer characterization

Method	Determination
Chromatography	
GPC	Molecular mass/distribution, composition
LC	of additives such as plasticizers,
GC	antioxidants, stabilizers
Light scattering	Molecular mass, shape and size
Ultracentrifugation	Molecular mass/distribution
Thermal analysis	
DTA/DSC	$T_g$ , $T_m$ , degree of crystallinity and purity
TG	Weight loss, degradation mechanism,
	reaction kinetics, activation energies,
	thermal stability, and organic filler
	composition
TMA/DMA	Mechanical properties
NMR ( $^1\text{H}$ and $^{13}\text{C}$ )	Structure, configuration, molecular
	dynamics
MS	Polymer composition and structure,
	degradation products
IR	Structure, composition
X-ray spectroscopy	
XRF	Filler composition
XRD	Filler identification, degree of crystallinity

GPC = gel permeation chromatography; MS = mass spectroscopy;  $T_g$  = glass transition temperature;  $T_m$  = melting point; TMA = thermomechanical analysis.

**Bitumens** Another important class of oil-based products is bitumens. Bitumen is a generic term defined by ASTM as a class of black or dark-colored (solid, semisolid, or viscous) cementitious substances, natural or manufactured. Bitumens are composed principally of high-molecular-mass hydrocarbons of which asphalt, tars, pitches, and asphaltite are typical. Commercially these are produced from the destructive distillation of coal, crude oils, and other organic matter. Asphalt occurs naturally either in rock or a lake. In the United States the terms bitumen and asphalt are interchangeable, whereas in the United Kingdom 'asphalt' is reserved for the naturally occurring product and bitumen is the residue from crude oil distillation. It is important to note that the compatibility of various classes of bitumen with other raw materials can vary widely. This can lead, for example, to marked differences in chemical and solvent resistance of the end product.

The typical composition of bitumen/asphalt used in roadbuilding, etc., is

Bitumen content	4–20%
Softening point	28–38°C
Penetration of 100 g at 25°C over 5 s (mm/10)	Too soft–360
Remainder	Graded mineral fillers (sand, sandstone or limestone)

**Analysis** *Elemental*: C, S, H, O, N (typically 79–88% C; 7–13% H; up to 8% S; 2–8% O; up to 3% N). *Trace metals*: Fe, Ni, V, Ca, Ti, Mg, Na, Co, Cu, Sn, Zn. *Molecular mass*: typically  $M_r = 500$ –2500. *Acid number*: typically 0.1–2.8 mg KOH per g. *Distillation range*: ASTM D3279. *Composition*: bitumen insoluble in paraffin naphtha (AASHTO T46 or ASTM D3279); bitumen soluble in carbon disulfide (ASTM D4). *Purity*: solubility, ash, water content (ASTM D95). *Softening point*: ASTM D36. *Flash point*: ASTM D92.

## Nonmetallic Inorganic Materials

Some important nonmetallic inorganic materials used in construction are cements; pozzolanic materials and slags; clays; calcium sulfates; and rocks, aggregates, sand, and glass.

### Cements

The Pocket Oxford Dictionary gives the first meaning of cement as 'Substance made by calcining lime and clay, applied as a paste and hardening into stony consistence ...'. This describes the principal cement

produced world-wide in hundreds of millions of tons, which is more precisely termed ordinary Portland cement.

Analysis is required right from the initial geological survey of a proposed raw material quarry through to the finished product. Ordinary Portland cement is essentially made from 4 parts of a calcareous material such as limestones and 1 part of an argillaceous material (e.g., clay or shale) and fired in a rotary kiln at  $\sim 1400^\circ\text{C}$ . The resulting clinker is rapidly cooled and then ground with  $\sim 5\%$  of gypsum to a specific surface area (measured by air permeability) of  $\sim 350\text{ m}^2\text{ kg}^{-1}$ . Gypsum is added to prevent a rapid ‘flash’ set when the cement is mixed with water.

The end-product consists of  $\sim 50\%$  tricalcium silicate (the main contributor to compressive strength development up to 28 days),  $25\%$  dicalcium silicate (contributes to long-term strength),  $10\%$  tricalcium aluminate (involved in setting, little contribution to strength),  $10\%$  tetracalcium aluminoferrite (little contribution to strength), and  $5\%$  gypsum. The relative proportions of the various phases principally govern cement performance.

When Portland cement is added to water, reactions take place to form calcium silicate hydrates and release calcium hydroxide. These hydrates act as the glue in mortars and concretes to hold the matrix together.

Chemicals can be added to the system to modify the rate of cement hydration; for example, sugars retard it and salts such as calcium chloride accelerate it (see Cement and Concrete Admixtures, below).

Of the non-Portland cements used in building, the most important is high-alumina cement (Ciment Fondu).

### High-Alumina Cement

High-alumina cement (HAC) is made from a mixture of limestone and bauxite melted together at  $\sim 1600^\circ\text{C}$  to produce a dark clinker. The clinker is ground to a similar specific surface area to Portland cement of  $\sim 350\text{ m}^2\text{ kg}^{-1}$ . The principal clinker phases are  $\sim 40\text{--}50\%$  calcium aluminate ( $\text{CaO} \cdot \text{Al}_2\text{O}_3$ ),  $5\text{--}10\%$  mayenite,  $[(\text{CaO})_{12}(\text{Al}_2\text{O}_3)_7]$ ,  $20\text{--}40\%$  brownmillerite  $[(\text{CaO})_4\text{Al}_2\text{O}_3 \cdot \text{Fe}_2\text{O}_3]$ , and  $5\text{--}10\%$  gehlenite  $[(\text{CaO})_2\text{Al}_2\text{O}_3 \cdot \text{SiO}_2]$ . Calcium aluminate is the principal strength-giving constituent, whereas mayenite reacts very rapidly and primarily governs the setting time. Gehlenite is undesirable and reacts only slowly with water. A small increase in the silica content of the raw materials can lead to a large increase in gehlenite content and silica must therefore be carefully controlled.

When HAC is added to water, calcium aluminate hydrates are formed very rapidly that can give Portland cement type 28-day strengths in one day. Unfortunately, in damp, warm, conditions these hydrates can ‘convert’ to a denser form, increasing the porosity of the matrix and thereby reducing strength. However, provided water:cement ratios of 0.4 or less are used, HAC-based concretes and mortars will be sufficiently strong even after conversion has taken place. The degree of conversion can be ascertained by differential thermal analysis/differential scanning calorimetry (DTA/DSC) or XRD.

In a manner similar to Portland cement, the hydration of HAC can be accelerated or retarded by the use of suitable admixtures. The most common accelerators are lithium salts, which can make HAC mortars set in a few minutes and the temperature rise to the boiling point of water. Hydroxycarboxylic acids are the most commonly used retarders.

HAC is used where rapid strength gain is required, in refractory applications and, with calcium sulfate, to form ettringite-based products either for shrinkage compensation or for high water:cement ratio grouts (e.g., 5:1). It is important to control carefully the relative proportions of HAC and calcium sulfate in ettringite-based systems to ensure optimum properties.

### Calcium Sulfoaluminate Cement

A promising ‘new’ cement that was discovered in the 1950s by Klein is based on calcium sulfoaluminate (CSA). It is made in a rotary kiln in a manner similar to Portland cement, but the raw materials used are bauxite, limestone, and calcium sulfate.

CSA cements can be ground with calcium sulfate and used in construction, where they are reported to be more durable than Portland cement, particularly in aggressive sulfate or chloride environments. With more calcium sulfate they can be used to produce ettringite-based products in a manner similar to HAC.

Like HAC, CSA-based cements react much faster with water than Portland cement and are therefore very useful for cold-weather working, for example down to an ambient temperature of  $-15^\circ\text{C}$ . However, CSA hydrates are not vulnerable to the HAC conversion problems.

### Chemical Cements

Even faster setting and strength gain can be achieved by direct acid–base reactions. For example, magnesium chloride and magnesium oxide (Sorel cement) react very rapidly in water to form

$\text{MgO} \cdot \text{MgCl}_2 \cdot 11\text{H}_2\text{O}$  and  $\text{Mg}(\text{OCl})_2$ . However, Sorel cement is attacked by water and it attacks steel.

The reaction of phosphoric acid (usually in the form of ammonium phosphate) with magnesium oxide in the presence of water gives magnesium phosphate cements. These are used for rapid repairs, for example of pot holes in busy roads.

### Pozzolans

Both natural and artificial pozzolans can be used to make cements by reaction with lime in the presence of water.

Natural pozzolans are usually volcanic in origin and the most widely used artificial pozzolan is the pulverized flyash (PFA) obtained from coal-fired power stations. Their composition varies widely but they are all silico-aluminate based.

They can be used alone with lime for low-cost bulk filling operations such as backfilling in old mine workings or to extend and improve the properties of Portland cement. Their use reduces permeability and heat of hydration, leading to improved durability. The downside is that strength development is slower. Analysis is important to discover the likely reactivity of the pozzolan and to determine whether it contains anything likely to be deleterious to its intended use.

Another material used to extend and improve cement systems is granulated ground blast-furnace slag (GGBFS). Approximately one ton of slag is produced per ton of iron and provided the quality is right it can be sold for about 2/3 of the price of Portland cement. The major components are 40–50%  $\text{CaO}$ , 35%  $\text{SiO}_2$ , 10–15%  $\text{Al}_2\text{O}_3$ , and 7–12%  $\text{MgO}$ .

For optimum reactivity with Portland cement it is important that the slag has the right chemical composition and a high glass content (>85%). The hydraulic index (eqn [1]) should be >1.0, preferably >1.5, where

$$\text{Hydraulic index} = \frac{\% \text{CaO} + \% \text{MgO} + \% \text{Al}_2\text{O}_3}{\% \text{SiO}_2} \quad [1]$$

The major oxides are determined by X-ray fluorescence (XRF) spectrometry and the glass content by XRD (BS 6699, 1992).

GGBFS is often used at up to 70% of a cement system, where its low heat of hydration, low permeability, and high chemical resistance make it particularly suitable for large concrete structures in aggressive environments, such as the Bahrain Causeway.

Blast-furnace slag can also be used with ~10% calcium sulfate and 5% Portland cement to produce supersulfated cement. However, it is much more commonly used to extend and improve Portland cement.

Another use of pozzolans and blast furnace slag is to reduce the available alkalinity of cement systems to prevent the occurrence of alkali aggregate reaction (see later).

**Analysis** Basically the analysis of cements and related materials is carried out for elemental composition, mineral morphology, and particle size distribution. In the past wet classical methods were used but these were largely superseded by modern instrumental techniques in the early 1970s owing to their higher efficiency, better accuracy, and greater cost-effectiveness. Such techniques include AAS, ICP-AES, XRF, XRD, DTA, DSC, scanning electron microscopy/energy-dispersive X-ray analysis (SEM/EDX) for elemental composition and laser light scattering, sedimentation, or the Coulter method for particle size.

XRF or AAS/ICP-AES is used to obtain an elemental composition such as percent  $\text{SiO}_2$ ,  $\text{CaO}$ ,  $\text{MgO}$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3$ ,  $\text{SO}_3$ ,  $\text{Na}_2\text{O}$ , and  $\text{K}_2\text{O}$ . For XRF analysis either a homogeneous glass bead is obtained by fluxing the milled sample with lithium tetraborate at 1100°C or a briquette is obtained by pressing. Glass beads overcome particle size effects and are most commonly used in R&D laboratories for nonroutine work. Briquettes are commonly used at production plants for routine analysis. Prior to AAS/ICP-AES analysis the sample is turned into the liquid state by a suitable method, e.g., fusion or reaction with hydrofluoric or mineral acids in a bomb calorimeter at 150°C.

Loss on ignition measurements and levels of calcium hydroxide, calcium carbonate, basic carbonates, and organic material (e.g. from grinding aids) are determined by thermogravimetric analysis. This technique shows weight loss at characteristic temperatures that can be related to the amount of various phases present. Free (uncombined) lime ( $\text{CaO}$ ) is determined by extraction with ethylene glycol and titration with  $0.1 \text{ mol l}^{-1}$  hydrochloric acid.

Qualitative and semiquantitative analysis of mineral phases and the estimation of glass contents are carried out by XRD. The mineralogical composition of ordinary Portland cement can also be estimated from the oxide analysis by the Bogue equation (ASTM C 150 (1986)). In addition, optical microscopy on polished sections has been very successfully employed over the years both to estimate the phases present and to provide insight into such things as kiln burning conditions.

The particle size distribution is usually measured by BS 410 sieves down to 45  $\mu\text{m}$  and by laser light scattering, sedimentation, or electrical (Coulter) techniques for particles finer than this. The cement must be suspended in a nonaqueous solvent such as dried isopropyl or butyl alcohols. SEM in conjunction with

EDX has also been used for the characterization of cementitious particles (e.g., OPC/PFA blends).

### Cement and Concrete Admixtures

Admixtures are chemicals that are added to cement and concretes to impart desirable characteristics such as retardation, acceleration, water reduction/workability, air entrainment, and impermeability. Admixtures can be classified as shown in Table 3.

Cement admixture companies are usually formulators rather than base chemical producers. Commercial admixtures are usually a synergistic blend of the above chemical types to impart a desired range of properties to the cement/concrete.

**Analysis** Admixtures are usually tested in the as-supplied condition in accordance with BS 5075 and/or ASTM C 494. The requirements of these standards include relative density, pH, solids content, chloride ion, ash, total alkali content, and occasionally a standard IR scan. For formulation purposes,

additional testing is carried out for composition and molecular mass by modern analytical techniques such as ultraviolet, Fourier-transform infrared (FTIR) spectrometry, LC, GLC, DTA/DSC, thermogravimetry (TG), and microscopy (for air entraining admixtures.) This very specialist work is unique to the author's laboratory.

For the analysis of hardened concrete the determination of admixtures is a difficult and seldom performed task. The above techniques have been used in the authors' laboratory. Water-reducing and retarding admixtures in hardened concrete have been successfully determined. The problem with the other admixtures is not the method of analysis but the difficulty of their extraction from the hardened concrete matrix owing to their tendency to form complexes. Sodium carbonate extraction followed by neutralization with an ion exchange resin is generally the preferred technique. This is usually followed up by modern analytical techniques. For air-entraining admixtures, microscopy is used to check that a good bubble size distribution has been achieved. SEM is being used for the characterization of mineral admixtures.

**Table 3** Cement and concrete admixtures

<i>Principal effect</i>	<i>Chemical types</i>
Retardation	Hydroxycarboxylic acids and their salts, e.g., citric, tartaric, gluconic, glucoheptonic, maleic, salicylic, tannic Carbohydrates, e.g., glucose, sucrose, hydroxylated polymers (corn starch syrup) Chelating agents, e.g., EDTA, NTA, borates Inorganic salts, e.g., zinc, lead, phosphates
Retardation/water reduction	Lignosulfonates, corn starch syrup
Water reduction	Salts of sulfonated naphthalene and melamine formaldehyde condensates, lignosulfonates
Acceleration	Calcium chloride, calcium formate, sodium nitrite, sodium carbonate, triethanolamine, calcium thiocyanate, Ca/Na thiosulfate, sodium aluminate, Na/K silicates
Air-entrainment	Lignosulfonate, alkyl aryl sulfonates, proteins, vinsol resin, ethoxylates, fatty acid derivatives
Air-detrainment	Organophosphates such as tributylphosphate (TBP), silicones
Permeability reduction	Silica fume, granulated ground blast furnace slag (GGBFS), pulverized flyash or fuelash (PFA), polymers such as styrene butadiene rubber (SBR), polymers and copolymers of ethylene and vinyl acetate
Water retention	Cellulose ethers, polyethylene oxide, vinyl polymers, and copolymers

### Clays

Clays were formed many millions of years ago by the weathering of rocks such as granite and gneiss. They are all silicoaluminates and their use depends on chemical composition and crystal structure.

Kaolin (38%  $\text{Al}_2\text{O}_3$ , 45%  $\text{SiO}_2$ , and 14% bound water) is predominantly used for chinaware and papermaking. It can be burned to  $\sim 900^\circ\text{C}$  to form meta-kaolin, which is another useful pozzolan for addition to Portland cement. Further burning to  $\sim 1100^\circ\text{C}$  produces mullite ( $3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$ ), which is used as a refractory.

Terracotta clays have a higher iron content than kaolin and are fired to make bricks, tiles, and pipes. In general, the higher the firing temperature, the lower the porosity of the final product and the higher the strength. Temperatures used range from  $970$ – $1150^\circ\text{C}$  for common bricks to  $1200$ – $1300^\circ\text{C}$  for engineering bricks. Bricks tend to be fairly porous to water; chemicals such as silicones can be used to improve water-repellency.

Montmorillonite clays are used in many construction grouts to impart thixotropic and water displacement properties. Another useful group of clay-like minerals are the illite micas e.g., muscovite,  $(\text{OH})_4\text{K}_2(\text{Si}_6\text{Al}_2)\text{Al}_4\text{O}_{20}$ , biotite,  $(\text{OH})_4\text{K}_2(\text{Si}_6\text{Al}_4)(\text{MgFe}_6)\text{O}_{20}$ , and phlogopite,  $(\text{OH})_4\text{K}_2(\text{Si}_6\text{Al}_2)\text{Mg}_6\text{O}_{20}$ . These can be used for making fireproof board, lamp chimneys, and electrical insulating materials.

**Analysis** The analysis of aluminate silicate clays is carried out to determine elemental composition, interlayer and bound water, particle size, and crystal structure.

Like cements, the composition of clay is established by either XRF or AAS/ICP-AES. However, it is necessary to modify the method of preparation of the fused bead by using a mixture of lithium tetraborate and lithium metaborate as the flux rather than lithium tetraborate alone.

Thermogravimetric (TG) analysis is used to determine the water content of clays. The weight loss at 110°C measures the interlayer water, whereas the bound water is lost between 400°C and 1000°C. The temperature at which bound water is lost is used in the identification of clays. For example, kaolin decomposes at 500–650°C to lose its bound water, whilst illite shows staggered weight loss between 400°C and 1000°C. Identification of clays is also carried out by IR spectroscopy in conjunction with XRD. The crystal structure is usually determined by XRD. Refractive index is also a very useful indicator of clay types.

### Calcium Sulfate

Calcium sulfate has many uses in the building industry, from the cement systems already mentioned to gypsum plasters and boards. It can occur naturally as anhydrite ( $\text{CaSO}_4$ ) or gypsum ( $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ ). Large amounts are also available as by-products from various industrial processes, for example, the manufacture of hydrogen fluoride and phosphoric acid, and the desulfurization of flue gases in coal-fired power stations.

When gypsum is heated to about 160°C it forms calcium sulfate hemihydrate ( $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$  – plaster of Paris). Further heating to about 190°C leads to the formation of soluble  $\gamma$ -anhydrite ( $\text{CaSO}_4$ ). At 380°C phase transformation takes place and  $\beta$ - $\text{CaSO}_4$  is formed.

When calcium sulfate hemihydrate is mixed with water it sets almost immediately to reform gypsum. Retarders such as tartaric acid or keratin can be added to slow down the reaction.

Anhydrite reacts much more slower than plaster, particularly if it contains an appreciable proportion of free lime. Accelerators such as potassium or aluminum sulfate can then be added. Anhydrite is often used in floor screed compositions.

**Analysis** Calcium sulfates are analyzed for particle size, type (crystalline form), pH, moisture content, and impurities such as free silica, lime (calcium oxide/hydroxide) and calcium fluoride. TGA and DTA

are complementary for the identification of calcium sulfate type. Moisture can only be measured by Karl Fischer titration. Using the elemental composition, thermal analysis data, and an XRD investigation, a probable composition for a calcium sulfate can be established.

Like cements, the elemental composition is determined by XRF or AAS techniques. The XRF bead is made using lithium tetraborate at 1050°C. Sulfide content cannot be determined by XRF. Sulfite,  $\text{SO}_3^{2-}$ , and sulfate,  $\text{SO}_4^{2-}$ , are safely analyzed by XRF.  $\text{Na}_2\text{CO}_3 + \text{K}_2\text{CO}_3$  fusion is carried out for Ca, Mg, Fe, and Al analysis by AAS. Lanthanum chloride is used as a sulfate interference suppressant. Gravimetric sulfate determinations are also carried out by precipitation as barium sulfate. The Leco Carbon–Sulfur Analyzer can also be used for quality control purposes. The fluoride is determined by XRF or a pyrohydrolysis method. The measurement of particle size distribution is carried out in a manner similar to that for cements and clays.

### Rocks, Aggregates, and Sand

Quarried stone has been used for many thousands of years as a building material. All was well until the industrial revolution started to put acidic gases such as sulfur dioxide into the air. The ensuing acid rain has severely damaged many limestone buildings. Analysis is therefore required of flue gases from industrial processes to ensure emission targets are being met. Old limestone buildings can also require protection.

Aggregates and sand are bound together with cement to make concrete. It is important that the aggregates and sands used are compatible with the cement. Modern dry-process Portland cements contain more of the alkali metals present in the raw materials because much less is lost with the flue gases. These alkali metals tend to be concentrated in the pore water in the concrete, leading to a pH of  $\sim 13.5$ . Such a high pH can attack certain siliceous aggregates and sands to form alkali metal silicate. These silicate gels swell in moist conditions by the process of osmosis, which then cracks the concrete. In severe cases this may lead to a structure having to be demolished. This process is known as the alkali silica reaction (ASR) and it is important that aggregates and sands are tested prior to use and the alkali content of the cement is known. Current building codes of practice limit the amount of alkali expressed as  $\text{Na}_2\text{O}$  equivalent to  $3 \text{ kg m}^{-3}$  of concrete.

**Analysis** A very important property of aggregates and sands for use in concrete is particle size. For a

concrete mix to have the right degree of cohesiveness and workability it needs a controlled aggregate/sand grading. The usual method of size analysis for sands and aggregates is by means of BS 410 test sieves. XRF, XRD, and AAS can be used for the elemental composition. Impurities such as clays, calcium carbonate, iron salts,  $\text{AlO}(\text{OH})$ , and illites can be estimated using instrumental methods. The shapes, sizes, and refractive indices of particles can also be studied by microscopy.

### Glass

Glass is manufactured by heating a mixture of silica sand and various metallic oxides/carbonates together in a furnace to a smooth and bubble-free melt at  $\sim 1500^\circ\text{C}$ . The usual glass used in the construction industry is soda glass. Formulations are very variable but typically might be:

$\text{SiO}_2$	70–75%
$\text{Na}_2\text{O}$	14–16%
$\text{CaO}$	8–13%
$\text{Al}_2\text{O}_3$	$1\frac{1}{2}$ –2%
$\text{MgO}$	2–5%

Fiber glass has a higher  $\text{Al}_2\text{O}_3$  content of up to 14% with an equivalent reduction in  $\text{SiO}_2$ . Increasing the  $\text{Na}_2\text{O}$  content reduces the melting point. Acid treatment of glass increases the  $\text{SiO}_2$  level to 99% by the removal of alkalis and other materials. This increases the melting point to  $1100^\circ\text{C}$ . Acid-treated glass is used to produce a cost-effective coarse fiber.

All glasses when they cool from the melting temperature pass through a range of temperatures at which crystalline compounds are likely to form. This process is known as devitrification. Once the glass has cooled to room temperature its viscosity is so high ( $10^{15}$  poise) that spontaneous devitrification is extremely difficult.

Glass is highly resistant to attack by water atmospheric pollution. However, persistent exposure to polluted atmospheres dulls the surface, increases the risk of devitrification, and leads to a loss in strength.

**Analysis** XRF, AAS, ICP-AES, and wet-chemical methods are used to determine the elements present in glass. Major elements are  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{SrO}$ ,  $\text{BaO}$ ,  $\text{ZrO}_2$ ,  $\text{Na}_2\text{O}$ ,  $\text{K}_2\text{O}$ ,  $\text{Li}_2\text{O}$ ,  $\text{MgO}$ ,  $\text{PbO}$ , and  $\text{CaO}$ . Minor elements include  $\text{Cu}$ ,  $\text{Co}$ ,  $\text{Cr}$ ,  $\text{Fe}$ ,  $\text{Mn}$ , and  $\text{B}$ .

XRF is carried out on pressed briquettes or fused beads. Lithium and boron cannot be determined by XRF. Fusion with sodium carbonate is carried out before the aqueous leachate is subjected to AAS,

ICP-AES, or flame emission photometry. Wet-chemical analysis can also be carried out on the above leachate.

## Metallic Inorganic Materials

Metals frequently used in construction are steels, alloy steels, aluminum, copper, lead, and zinc. The prevention of metal corrosion is extremely important.

### Steels

The first stage in the production of steel is the manufacture of iron from iron ore in a blast furnace. Molten iron is drawn off from the bottom of the furnace. Impurities are removed with the slag, which has already been mentioned in connection with cements.

Oxygen is now blown through the molten iron to oxidize waste constituents. The resulting pure iron is termed 'wrought iron', which is used for gates, fencing, and the like.

Carbon, manganese, chromium, nickel, titanium, molybdenum, vanadium, and tungsten can be added to the molten pure iron to form various steels.

Steels with a very low carbon content ( $< 0.2\%$ ) are softish and ductile. Mild steel accounts for 90% of the output of the steel industry. In the building industry it finds uses in reinforcement bars and mesh for concrete owing to similar thermal coefficients of linear expansion, and in steel pipes, steel sheeting, etc.

Structural steels for use in beams, girders, etc., are generally made with a carbon content of 0.15–0.25%. They also include a number of other constituents, such as up to 1.5% manganese and up to 0.50% chromium. Sulfur and phosphorus must be less than 0.05% each. High-carbon steels (0.5–2.0% C) are used for hammers, drills, cold chisels, etc.

### Alloy Steels

Elements such as chromium, manganese, nickel, tungsten, vanadium, silicon, and molybdenum are added to steels to obtain alloys with improved properties, for example strength, elasticity, hardness, abrasion resistance, rust resistance, and chemical resistance.

Manganese increases tensile strength and hardness at the expense of ductility. Chromium and nickel improve strength and toughness and their alloys are used for high-tensile steel bolts, for the manufacture of steel wire and cable for prestressing and post-tensioning, and for the construction of springs. Tungsten, vanadium, molybdenum and cobalt are used for

cutting steels that maintain their hardness almost to red heat.

Chromium and nickel are added to form stainless steels. When chromium is exposed to a corrosive atmosphere, an adherent film of chromium oxide ( $\text{Cr}_2\text{O}_3$ ) is formed. Nickel serves to improve the stability of the oxide film. Martensitic stainless steels contain  $\sim 0.1\text{--}0.4\%$  carbon and  $\sim 14\%$  chromium. They are very hard and can be tempered. Their use is in stainless-steel cutting tools.

Austenitic stainless steels are by far the most common and contain  $\sim 18\%$  chromium and  $8\%$  nickel, hence the term 18/8 stainless steel. The austenitic structure, which is the solid solution of iron carbide and all the metal additives in iron, is stabilized at all temperatures, producing a soft and flexible product. It is used for fume hoods, decorative cladding, and architectural features.

Ferritic stainless steels contain  $0.1\%$  carbon and  $15\text{--}20\%$  chromium and have a high elongation figure. They are used almost exclusively for pressed and deep-drawn articles such as kitchen sinks.

## Aluminum

Aluminum is the third most abundant element in the earth's crust. Unfortunately, it is mostly present as complex silicates and clay from which extraction is uneconomic.

Aluminum production is therefore based on bauxite, with an alumina content of at least  $55\%$ . Bauxite is powdered, calcined, milled with strong caustic soda (sodium hydroxide) and treated with steam at 5 bar. The sodium aluminate formed is filtered and diluted and a small quantity of alumina is added for seeding purposes. The pure aluminum hydroxide that precipitates is filtered off, roasted, and then electrolyzed in an electric furnace with cryolite ( $\text{Na}_3\text{AlF}_6$ ) used as a flux at  $1000^\circ\text{C}$ . Carbon anodes are used and are rapidly consumed. The whole process is very energy intensive.

The electrical resistance of aluminum is 1.5 times that of copper; however, its density is only  $2700\text{ kg m}^{-3}$  compared with  $8900\text{ kg m}^{-3}$  for copper. Hence the conductivity of aluminum is twice that of copper per unit weight. It is therefore used widely for power transmission cables. Aluminum is in general more resistant to corrosion than iron and steel owing to the formation of a well-adhering coating of aluminum oxide.

Aluminum is readily attacked by alkalis. The rate of attack by wet cement is rapid, with hydrogen liberated during the reaction. This reaction is made use of in light-weight cement block production and

gas-forming grouts that use the gaseous expansion to overcome plastic settlement.

The primary aluminum alloys used in building are as follows.

1. Manganese alloys containing  $1.2\%$  Mn. These are stronger than pure aluminum and more corrosion resistant, with no loss of workability. They are widely used in cladding and roofing materials.
2. Magnesium alloys are strong, ductile, and extremely corrosion-resistant. They are used for tubular scaffolding and the like.
3. Magnesium silicide alloys contain up to  $1.5\%$   $\text{Mg}_2\text{Si}$ . They are used for extrusions such as window sections.

## Copper

Copper usually occurs in sulfide ores intimately mixed with iron sulfides and many other compounds. The ores are ground and the copper is concentrated by froth flotation. The concentrate is heated in a reverberatory furnace where a high-density molten copper 'matte' and a low-density molten slag are formed. The molten matte is separated from the slag and transferred to a converter where air is blown through, allowing the oxidation of copper sulfide ( $\text{Cu}_2\text{S}$ ) and other compounds to copper. Copper can then be either 'fire refined' for use in alloys or 'electrolytically refined' for high-purity grades.

Copper is extremely resistant to atmospheric corrosion as it rapidly forms a complex green hydrated copper(I) oxide/carbonate film that prevents further corrosion. Copper is very suitable for underground services as it is extremely resistant to attack. Corrosion troubles occur when copper and steel pipes are joined together, because copper induces corrosion in steel objects joined to it by electrochemical action.

Copper has good chemical resistance, but is attacked by concentrated sulfuric acid, nitric acid and ammonia.

Copper is mainly used in the building industry for water and gas pipes. Its corrosion resistance and ease of bending and joining with good frost resistance make it eminently suitable. Copper sheet is used in roof coverings and in hot water tanks and domestic boilers. The high electrical conductivity of copper is used to good effect in most electrical cables.

**Brasses** Brasses are alloys of copper and zinc. The most popular is 60/40 used for the manufacture of a wide range of fittings.

**Bronzes** Bronzes are alloys of copper and tin, usually with some other elements such as phosphorus added. Normal phosphor bronze contains  $5\text{--}6\%$  tin

and traces of phosphorus. It is used for woven wire filters and screens. Bronze containing 12% tin is used for ornamental doors and bronze fittings. Copper–nickel–silica alloys are used for architectural features such as shop windows and counters.

### Lead

Lead occurs as galena ( $\text{PbS}$ ), cerisite ( $\text{PbCO}_3$ ), and anglesite ( $\text{PbSO}_4$ ). Galena is the most common. Lead ores are usually roasted and then reduced in a blast furnace with coke.

Purification is carried out by adding zinc, which removes silver (Parkes process), or by electrolysis in a solution of lead hexafluorosilicate and hexafluorosilicic acid (Betts process).

One of the most useful properties of lead is its ability to absorb nuclear and X-ray radiation. Lead has good chemical resistance but is attacked by nitric and organic acids. Lead is extremely resistant to atmospheric corrosion as it rapidly becomes covered with an impervious film of oxides, carbonates, and sulfates.

Lead was used for water pipes and other plumbing components. However, it is no longer installed for the transportation of drinking water. In soft-water areas there are programs to replace existing water authority lead pipes with plastic owing to possible permanent adverse health effects amounting from even low levels of lead in drinking water.

Lead is better than copper for roofing on account of its durability, but it is expensive and relatively heavy. Lead is also widely used for flashings and trimmings, anti-vibration mats, and sound proofing.

### Zinc

The most common ore is zinc blende ( $\text{ZnS}$ ), which is found in association with lead, iron, and other sulfides.

Before smelting, zinc sulfide is usually concentrated by a float and sink method. The zinc sulfide is then roasted to form zinc oxide, followed by reduction with carbon and/or carbon monoxide. Zinc metal is distilled off.

About half the zinc produced is used as a coating metal. The most common method of coating is hot-dip galvanizing. Iron or steel objects are degreased, followed by immersion in a bath of molten zinc at  $455^\circ\text{C}$ . Zinc protects the base metal from corrosion by acting as a sacrificial anode. Other methods are molten zinc spraying, electroplating, sheradizing (objects are heated in powdered zinc just below its melting point at  $\sim 380^\circ\text{C}$ ), and painting with zinc-rich paints.

### Corrosion of Reinforcing Steel

Corrosion of metals is a problem that costs many millions of US\$1£ per annum. In building it is therefore essential to minimize the likelihood of corrosion at the design stage in a cost-effective manner.

Corrosion is an electrolytic process that requires an anode, a cathode, and an electrolyte. In reinforced concrete the reinforcing steel becomes covered in a passivating layer of  $\gamma$ -iron oxide formed in the high-pH environment ( $\sim \text{pH } 13$ ) provided by the Portland cement. Unfortunately, the high pH can be neutralized by acidic gases such as carbon dioxide in the atmosphere. Once the pH in the concrete drops below  $\sim 10$ , generalized corrosion of the steel will take place in the low-pH area.

This phenomenon can be overcome by ensuring good concrete cover over the steel, using high-quality low-permeability, well-compacted concrete, and coating the concrete with a surface coating that prevents the ingress of carbon dioxide while allowing the passage of water vapor.

The chemical test for this type of corrosion is very straightforward. A lump of concrete is freshly broken out from the corroding area and sprayed with a 1% phenolphthalein solution in isopropyl alcohol. If the phenolphthalein remains colorless, then the alkalinity of the concrete has been neutralized. If the phenolphthalein goes purple (i.e., the concrete is sufficiently alkaline) *but* reinforcement corrosion is observed, then the far more serious problem of chloride attack is likely to be occurring. An explanation of the mechanism of chloride attack follows.

When chlorides reach the steel the passivating layer is broken down and a small anode is set up. This positive anode attracts further chloride ions, leading to local concentration and a lowering of pH. The steel away from the area of attack acts as a large cathode. This type of corrosion is more serious than the generalized corrosion caused by carbonation of the concrete because pits are formed and steel cross-section is rapidly lost, which can lead to structural failure.

Chlorides can be present in concrete from a number of sources. Calcium chloride is the best accelerator for Portland cement and was frequently added in precast concrete in the 1960s to maximize plant throughput. Chlorides will be present if unwashed marine dredged aggregates are used or seawater is used for mixing. A small amount of chloride can also be present in the Portland cement. Even after care was taken to minimize chlorides present in concrete, structures still started to show corrosion damage within a few years of completion. This is caused by the ingress of chlorides into the concrete

**Table 4** Major and minor constituents of various metals and alloys

Metals/alloys	Constituents	
	Major	Minor
Iron and steel	Fe, C, S, Si, Mn, P, Cr, Ni, Co, Cu, Nb, W, V, Mo	Sn, Sb, Zr, Pb, As, Bi, Ti, Mg, Te, Ce, La, V, Al
Copper	Cu	Sn, Pb, Zn, Fe, Ni, Al, Si, Mn, As, Bi, Sb
Aluminum/Al alloys	Al, Si, Mg, Pb, Zn, Cu, Ni, H	Fe, Mn, Cr, Ti, Sr, Zn, Na, Bi, V, Ca, P, Be, Li
Brass	Cu, Zn	Sn, Pb, Fe, Ni, Al, Si, As, Mn, Bi, Sb, P, S, Cr, Co, Mg
Zinc	Zn	Pb, Mg, Al, Cd, Fe, Sn, Cu, Ni, Mn
Lead	Pb	Sb, Sn, Bi, Cu, As, Ag, Zn, Cd, Ni, Te, Ca

from the use of deicing salts or from marine environments. The permeability of concrete to chlorides can be minimized by using a penetrating siloxane sealer, low water/cement ratios, and a PFA- or slag-modified cementitious phase.

Analysis is required to ensure all materials used in the manufacture of concrete contain less than the specified amounts of chloride, to assess the depth of chloride penetration into concrete from external sources, to determine the water/cement ratio used, and to describe the type of cement employed.

#### Analysis of Metals

The direct-reading spectrograph is still a widely used instrument for analysis for metals and most low-level residual impurities using the ASTM E414-7 method. The technique consists of briquetting the sample in the form of chips, drillings or powder, followed by excitation in a d.c. arc opposite a high-purity metal rod.

Since the 1960s new techniques such as AAS, ICP-AES, and XRF have been used for plant control and environmental measurements. Iodometric titrations are still used in many industrial laboratories, but the newer methods are more rapid and convenient. Other techniques including colorimetry, electrodeposition,

X-ray microprobe, neutron activation, and electro-analytical methods have been mentioned in the literature. For irons and steels the carbon and sulfur level is determined by a Leco carbon/sulfur analyzer or similar in addition to the elemental analysis. Similarly, the hydrogen content is measured in aluminum by a hydrogen analyzer. Table 4 summarizes the elements determined for various metals and alloys.

### Introduction

Although cadmium emissions into the environment have generally decreased in recent years, they still constitute a severe environmental problem in many areas, putting human health at a risk. Since Cd mobility and toxicity depends on its chemical form, the speciation analysis of Cd seems to be the more realistic way for the understanding, diagnosis, and eventual treatments for such potential health problems. The importance of Cd in living organisms relates not only to its bioaccumulation but also to its active role as an inducer of the biosynthesis of metallothionein. For this reason, the interest of researchers has moved recently from environmental samples toward the biochemical speciation analysis of Cd in biological fluids and tissues. Today, Cd speciation analysis in bioinorganic analytical chemistry includes determinations of the bioinorganic moiety (e.g., Cd at very low levels) and the bioorganic ligand (e.g., proteins, polypeptides, oligopeptides, etc.). Mass spectrometry (MS) techniques are critical, as we will see later on, in such studies that eventually aim to understand the role that Cd and its species play in living organisms. Also, the application of isotope dilution analysis to the precise quantification of such Cd species will be finally addressed in this article.

### Cadmium Sources and Toxicity

Apart from natural emissions, Cd is usually found in the environment because of several anthropogenic activities. Due to its chemical and physical properties, Cd is widely used in special alloys (e.g., copper-, tin-, lead-, or zinc-based alloys), pigments (as Cd sulfide and selenide), stabilizers (e.g., Cd incorporated into poly(vinyl chloride)), NiCd batteries and coatings (e.g., steel, aluminum and other non-ferrous metals). Of course, the manufacturing,

**Figure 1** Relative importance of the various cadmium sources to human exposure.

increasing use, and disposal of products containing Cd will eventually release it into the environment. However, major Cd emissions into the environment arise from products to which Cd was not intentionally added (i.e., it was an impurity). For instance, the combustion of fossil fuels, iron and steel production, and the use of phosphate fertilizers in agriculture constitute the main anthropogenic sources of Cd emissions to air, water, and soil. The relative importance of the various Cd sources to human exposure is illustrated in Figure 1.

The ingestion of foods, e.g., plants grown in soils containing Cd or meat from animals that ingested those plants, and inhalation, e.g., cigarette smoking or from Cd occupational exposure, are considered the main routes of human exposure to Cd, the maximum tolerable daily intake being 1 µg per kg of body weight (World Health Organization).

Concerning its toxicity, Cd is known to accumulate in the human kidney for a relatively long time and it causes serious renal dysfunction. Moreover, breathing high levels of Cd causes severe damages to lungs and several studies have pointed out its likely role in human carcinogenesis.

Therefore, constant Cd emissions due to anthropogenic sources has led to severe environmental pollution problems and increased interest on studying the mechanisms of this metal toxicity.

### Cadmium Speciation, What and Why?

In general, identification and quantitation of elemental species provide very important information about

its impact on the environment, its bioaccumulation, and toxicological effects. This fact has led to the development of the so-called 'speciation analysis'. As for other toxic elements, Cd toxicity depends upon its physicochemical form; hence, the determination of its different chemical forms is paramount for a correct evaluation of the environmental and health risks posed by Cd. For example, inorganic species of Cd are more toxic than organic ones (and, of course, among the inorganic ones,  $\text{Cd}^{2+}$  is most toxic).

### Cadmium Speciation in Environmental Samples

Most Cd speciation studies available have been carried out in biological systems, while comparatively little attention has been paid to the speciation of this metal in environmental samples and matrices (e.g., water samples, soils, sediments, or fly ash). Moreover, most of such studies devoted to Cd species in the environment are closer to fractionation than to real chemical speciation analysis. Fractionation, defined by International Union of Pure and Applied Chemistry (IUPAC) as "the process of classification of an analyte or a group of analytes from a certain sample according to physical or chemical properties", has been used as a separative step ('sequential extraction' procedures and rough classification of the total metal content into fractions of different toxicities) in soils, fly ashes, and sediments evaluated from the point of view of their environmental or toxicological risk. Typical sequential extraction procedure usually allows classifying Cd in at least four fractions: exchangeable, reducible, oxidizable, and total residual fraction. In soils and sediments, several studies pointed out that Cd shows a strong binding to organic matter (e.g., to humic and fulvic acids) and a relative sorption to clay, which limited its bioavailability.

In water samples, Cd speciation studies most often comprise the physical separation of  $\text{Cd}^{2+}$  from its inorganic or organic Cd complexes, along with the analysis in the sample of other elements, including Cu, Co, Fe, Mn, Ni, Pb, and Zn. The determination of  $\text{Cd}^{2+}$  in environmental samples usually involves a preconcentration step, which also serves to remove the sample matrix. Thus, this step is commonly accomplished for speciation in waters by passing the water sample through a column packed with an appropriate chelating cation exchanger. Final determination of Cd, released with a convenient reagent, can be achieved by atomic absorption spectrometry (AAS), electrothermal atomic absorption spectrometry, inductively coupled plasma-optical emission spectrometry (ICP-OES), or ICP-MS. Recently, flow injection analysis systems have been recommended

for carrying out the preconcentration step and the final release of the metal for transport to the specific (atomic) detector.

The preconcentration step is in particular useful in a saline matrix (e.g., seawater Cd speciation). For instance, ICP-MS is susceptible to polyatomic ion interferences from seawater and its performance is much better after such a matrix removal step.

Finally, electrochemical techniques including voltammetric techniques and ion-selective electrodes (ISE) for Cd have also been reported in the literature for 'free' Cd determinations in waters, allowing the differentiation between labile Cd species from strong Cd complexes (e.g., bound to humic and fulvic acids and colloids). Mercury is still the electrode material of choice for detection of Cd due to its large hydrogen overvoltage and its remarkable reproducibility.

The development of routine and easy handling procedures for continuous and real-time speciation of trace metals in waters has led, in the last years, to the development of microsensors coupled to voltammetric techniques. Microelectrodes offer several advantages for speciation measurements in real-world samples, including their application in low ionic strength media (e.g., freshwaters), reproducibility, and sensitivity. Some Cd speciation studies carried out in river waters, heavily loaded with suspended material, using microelectrodes demonstrated that most of Cd was associated with colloidal material. In addition, this technique also enables the determination of the corresponding complexation stability constants for Cd and protons.

### Speciation of Cadmium in Biological Material

Speciation analysis of Cd (as of other metals, e.g., Cu and Zn) in biological materials has become a real challenge, in trying to understand the role of the metal in living organisms. In this area, most investigations have focused so far on Cd speciation in metal-proteins or metal-peptides complexes (e.g., metallothioneins and phytochelatins) in biological tissues. Cd speciation in biological fluids (e.g., serum, urine, and milk) has received lesser attention.

Metallothioneins (MTs) are a group of small cysteine-rich proteins that exhibit high affinity for some metal ions such as  $\text{Cd}^{2+}$ ,  $\text{Zn}^{2+}$ , and  $\text{Cu}^{+}$ , forming characteristic metal-thiolate clusters. Apart from homeostatic functions, MTs play a role in the detoxification of toxic metals (e.g., Cd, Hg, and Ag). Thus, MTs can chelate  $\text{Cd}^{2+}$  and accumulate it in the form of nontoxic Cd-MT complexes. The fact that multiple forms of MT exist in many biological systems has lead to a great interest in studying

individual forms of MTs (the so-called MT isoforms) in order to clarify their actual biological role. In this sense, Cd speciation studies in MTs are generally concerned with the complexation of Cd with these individual forms.

MTs were first isolated from equine kidney, but they have widely been found throughout the animal kingdom. In typical mammals, there are two main isoforms, MT-1 and MT-2, named in the order of their elution from an anion-exchange column. Several experiments under Cd exposure, as well as under natural conditions, have demonstrated that Cd binds to both MT isoforms, in combination with copper and zinc. The relative affinity of such metal ions for MTs is in the following order:  $\text{Zn}^{2+} < \text{Cd}^{2+} < \text{Cu}^{+}$ .

MTs in invertebrates have also been named MT-like proteins, MLPs, because they differ significantly from those of vertebrates. In spite of these differences, both vertebrate and invertebrate MTs have been isolated for Cd speciation analysis using similar analytical procedures. A typical preparative procedure to extract MTs from animal tissues is given in Scheme 1.

On the other hand, it is known that Cd accumulation in soil and water now poses a major environmental problem due to various industrial and agricultural activities (as reported in previous sections). In fact, the first papers on Cd speciation were mainly focused on such environmental issues.

The use of metal-accumulating plants to remove this toxic metal from soils and water streams has been proposed as a possible remediation of this problem. This type of environmental restoration is termed phytoremediation. In plants, Cd appears to accumulate preferentially in sulfhydryl-rich peptides named phytochelatins (PCs). PCs have the general formula  $(\text{GluCys})_n\text{Gly}$  where  $n$  is between 2 and 11.

It is known that these peptides are induced in plants exposed to  $\text{Cd}^{2+}$ , which in turn may form PC–Cd complexes removing toxic-free  $\text{Cd}^{2+}$  from the solution.

As MTs, PCs are synthesized in plants in response to other metals also (e.g., Cu, Ag, Pb, Zn, or Hg), but the study of PCs in connection with Cd is most important today because this metal is the most efficient inducer of PCs in plants.

In conclusion, the need to speciate Cd contents in both MTs and PCs is of great scientific and analytical interest nowadays.

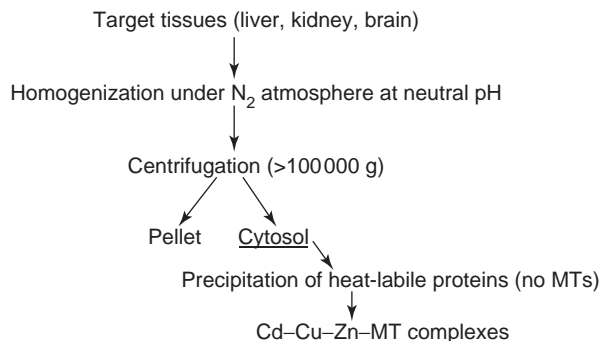

### Cadmium Speciation in Metallothioneins and Related Molecules by Electrochemical Techniques

Electrochemical techniques were extensively used to measure ‘free’ Cd in waters. In the case of MTs and related molecules, the amino acid chain is electroactive due to the presence of thiol groups. Moreover, the reduction of  $\text{Cd}^{2+}$  is electrochemically reversible at the mercury electrode and, therefore, it is possible to obtain two different responses simultaneously for a given sample. In addition, the electrochemical response depends on the chemical form of the element and allows one to easily monitor changes of the different species in solution. At present, many studies on the electrochemical behavior of Cd–thioneins have been reported. Most of them used mercury as the working electrode and so the polarograms of MTs exhibit one peak that is attributed to the oxidation of the mercury electrode in the presence of the Cd–thionein complexes.

Some advantages of electrochemical techniques are that the redox potentials of MTs at the electrode surface or the electrode solution interface can be accurately determined, allowing to probe the electroactive groups that undergo the electron transfer reaction. On the other hand, the precise control of the electrode potential allows examining Cd release from the MT or Cd uptake by the MT molecules.

Recently, electroanalysis of Cd-complexation with different mammalian MTs (e.g., rabbit liver, horse kidney, and human kidney) has become more frequent. The study of cysteine-containing peptides such as glutathione and MTs peptidic fragments (mainly  $\alpha$ -domain of mammalian MTs), in the absence and in the presence of  $\text{Cd}^{2+}$ , has been carried out by means of several electrochemical techniques such as differential pulse polarography (DPP), linear sweep voltammetry, cyclic voltammetry, direct current

#### Sample treatment scheme

**Scheme 1** Typical sample procedure to obtain the cytosolic fraction that contains Cd–MT complexes. Oxidation of metal–MTs complexes is avoided with N<sub>2</sub> atmosphere and the inclusion of reducing agents in the buffers. Cytosol can suffer a heat step in order to termocoagulate non-MTs proteins.

polarography, square wave voltammetry (SWV), and anodic stripping voltammetry. For instance, DPP is a good technique for providing information about complexation properties. This technique has been applied to *in vitro* studies of synthetic MTs in order to understand the properties of Cd–MT complexation. Additional advantages of DPP and SWV are that these techniques allow very low metal concentrations to be tested, where potentiometry with ISE are not reliable.

In real samples, the voltammetric responses of differential pulse anodic stripping voltammetry have been applied to investigate the Cd-binding properties in MLPs from mussels. The existence of two different Cd–MLP complexes was thus demonstrated.

## Cadmium Speciation Analysis Using Hyphenated Techniques

As for other elements, the analytical techniques developed to tackle real-life Cd speciation problems are mainly hybrid techniques today. Hybridization is achieved by coupling a powerful separation technique to an element-specific detector allowing the online determination of Cd in the separated species. For instance, the coupling of liquid chromatography (LC) with AAS or with ICP-OES turned out to be especially useful for the Cd-speciation in proteins in contrast to more classical offline methods. Nevertheless, ICP-MS has taken over as the most powerful atomic technique for the simultaneous determination of trace metals, due to its extreme sensitivity, capability of giving isotopic information, and a relative lack of interferences. Due to such characteristics, liquid chromatography LC–ICP-MS is today the preferred hybrid approach in speciation of Cd, although capillary electrophoresis (CE)–ICP-MS has also been proposed. Of course, ‘organic’ MS should be used to identify and characterize the particular bioligand (e.g., protein) binding Cd. In this latter vein, matrix-assisted laser desorption ionization–time-of-flight and electrospray ionization–tandem mass spectrometry (ESI–MS/MS) are increasingly used in speciation work. All those ‘hyphenated techniques’ have been successfully employed for the separation and characterization of Cd-containing metalloproteins and metal–peptides complexes (such as MTs and PCs, respectively).

### LC Coupled to ICP-MS

Cadmium species in metalloproteins can be separated in a first step by size exclusion chromatography (SEC) according to their size (and, to a lesser extent, their shape) enabling the separation of higher

molecular and lower molecular weight Cd-containing proteins. Although the online coupling of (SE)–LC with ICP-MS allows real-time element-specific detection of various Cd-containing molecular weight fractions, the SEC resolution is insufficient for Cd–MT isoforms’ discrimination. Further separation studies of a given MT fraction, using complementary chromatographic separation techniques (e.g., anionic exchange, reverse phase, or capillary zone electrophoresis, (CZE)), are needed.

On the other hand, (SE)–LC coupled to ICP-MS, and also coupled to UV and AAS detection, have been used to investigate PCs and PC–Cd complexes. Unfortunately, SEC does not provide enough resolution to separate all individual PC–Cd complexes. Thus, SEC has become a sort of preparative step to separate the MT and PC pools from the matrix of the sample.

Although few studies have been carried out for Cd speciation in biological fluids (e.g., human serum, human milk, cow milk, and formula milk), in cow and formula milk Cd seems to be bound to caseins while in human serum Cd appears to be complexed by ceruloplasmin, a well-known glycoprotein for metal storage.

On the other hand, anion exchange (AE)–LC has been used for the separation of the two main MT isoforms (MT-1 and MT-2) based on their different negative charge at neutral pH. This technique, especially the so-called anionic exchange fast protein liquid chromatography (AE–FPLC), offers good resolution. The use of FPLC with a strong anion exchanger allows the fast isolation of proteins, peptides, and amino acids with high efficiency. The coupling of AE–FPLC to ICP-MS has been successfully applied for the isolation and characterization of Cd–metalloproteins in both invertebrates (MLPs in mussel tissue) and in vertebrates (fish liver and kidney MTs), indicating the urgent need of Cd speciation studies in environmental issues.

Once a fraction is separated (e.g., MT-1), further separation of MT isoforms is possible using reverse phase (RP)–LC, which is the preferred technique in terms of resolution because the packing material is usually free of ligands for metals. The hybrid technique RP–LC–ICP-MS has been used, in fact, for such speciation purposes in biological samples as liver, kidney, and brain MTs, the main limitation being the loss of sensitivity in the ICP-MS due to the presence of the organic modifiers.

### CZE as a Tool for Cadmium Speciation

CZE is a well-established separation technique for metalloproteins and metal-binding peptides owing to

its high separation efficiency, the small sample requirement (several nanoliters), short analysis times, versatility in modes of operation, and the absence of packing susceptible to interactions with metals affecting the complexation equilibria. Many authors have shown the analytical potential of CZE as a high-resolution technique for the speciation of Cd-MTs. Cd-MTs can be well resolved using uncoated fused-silica capillaries under neutral or slightly alkaline pH. Under these conditions, MTs (pI values in the range of 3.9–4.6) have negative charge and move counter-electroosmotically toward the inlet end in normal polarity conditions. However, they can be detected due to the electroosmotic flow which is higher in magnitude than the electrostatic force they experiment toward the anode. CE-ICP-MS separations are particularly difficult because the different MT isoforms and subisoforms appear very close to each other in the timescale. Thus, any suction effect in the nebulizer would degrade the separation achieved. Moreover, the low flows emerging from a CE capillary do not match those required in typical ICP-MS nebulization devices. For this reason, the design of the interface between CE and ICP-MS is critical.

Due to nanoliter per minute flows of CE the concentration-based detection limits are seriously degraded in comparison with those obtained by LC, limiting the application of CE in Cd speciation analysis of real samples. In any case, there are CE strategies (e.g., large volume sample stacking) that are able to preconcentrate the analytes and have been successfully applied to real samples in order to improve the detectability of Cd species in MTs by CE-ICP-MS. **Figure 2** shows typical electrophoretic results by a hybrid technique for speciation of Cd-MTs in fish samples of environmental monitoring interest.

The use of CE coupled to high-resolution ICP-MS instruments has also been reported in the literature. It has been shown that Cd-MT complexes can be separated by CE and different metallic elements and sulfur can be simultaneously detected by using a high-resolution sector field (SF) ICP-MS detector operating at medium resolution to avoid polyatomic interferences that affect the determination of sulfur.

#### Gel Electrophoresis with Laser Ablation Applied to Cadmium Speciation in Proteins

Gel electrophoresis is a well-known separation technique for complex media such as proteins. However, classical modes of detection (including dye staining, immunoreaction with antisera, and autoradiography) do not allow the detection of metal-protein complexes.

**Figure 2** Electrophoretic separation of fish Cd-MTs complexes (real sample) by CE-ICP(Q)MS. Signals for  $^{111}\text{Cd}$  and  $^{114}\text{Cd}$  were monitored showing that Cd binds two main MT isoforms. (Alvarez-Llamas G, Fernández de la Campa MR, and Sanz-Medel (2003) Sample stacking capillary electrophoresis with ICP-(Q)MS detection for Cd, Cu, and Zn speciation in fish liver metallothioneins. *Journal of Analytical Atomic Spectrometry* 18: 460–466; reproduced from The Royal Society of Chemistry.)

In the context of chemical speciation, a new hyphenated technique, laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS), in combination with gel electrophoresis, appears as an emerging and powerful tool for metal complexation studies of proteins, giving multielement information about metals bound to the previously separated metalloproteins.

After the separation of the protein has taken place by one- or two-dimensional electrophoresis, gels are dried and subjected directly to LA-ICP-MS in order to detect, map, and quantify metal distribution in individual stains (compounds). In brief, a spot of the sample is ablated by the laser and the ablated plume is brought to the plasma by a continuous gas flow, generally argon. Then, ICP-MS gives the multielemental composition of the protein present in the ablated site. This method has been already reported for Cd speciation in MTs and in other Cd-binding proteins from bacterial extracts. Metal protein patterns in gels coming from cells grown under Cd-stress conditions can be compared very quickly to nonstressed cultures to investigate induction of MTs by metals.

## Methods for Bioligand Identification and Determination

ESI is a soft ionization technique (in contrast to ICP) and can be used to produce primarily intact protonated molecular ions of peptides and proteins. This technique, in combination with MS or tandem mass spectrometry (MS/MS), has been investigated in the last years for the ionization of metal-containing species (including Cd species) to obtain precise information of molecular weights and structural characterization of such bioligands at trace levels in complex matrices.

In ESI, peptides and proteins molecules are protonated, generating from single to multiple charged ions (e.g.,  $[M + H]^+$ ,  $[M + 2H]^{2+}$ , ...,  $[M + nH]^{n+}$ ). The number of protons attached to the molecules depends on their molecular mass, but generally, metal-containing species with mass up to 1000 Da are singly protonated, while polypeptides, proteins, and their metal complexes became multicharged ions. Thus, Cd-containing proteins as MTs (6–7 kDa) usually acquire charges of +4 and +5 in the ESI. The ions generated are sampled into the high-vacuum region of the mass analyzer, most often a quadrupole, where they are detected according to their  $m/z$  ratio. In this way, the resolution even in the simple quadrupole allows to distinguish  $\pm 1$  Da of molecular mass, enabling to differentiate very similar compounds (e.g., charged protein isoforms and their metallated complexes), which allows the confirmation of the presence of known compounds and their metal complexes. On the other hand, when identifying and characterizing unknown chemical species, including Cd-containing peptides or proteins, ESI-MS/MS (e.g., a triple-quadrupole mass spectrometer system) is needed.

The application of LC online with ESI-MS is especially attractive for the speciation analysis of Cd and Zn complexes. Metallated complexes such as MTs may suffer from several artifacts in their chromatographic separation due to the presence of those metals. For instance, the presence of other metals may modify the retention of the complex Cd–Zn–MTs on a RP column. As an alternative, ESI-MS with pH control can help in the analysis of metals in native and reconstituted metalloproteins, in order to exactly elucidate which biocompound binds Cd, how many atoms of Cd per bioligand molecule are bound, and what is the combination with other metals (e.g., Zn and Cu) in such molecules. In this line, samples of rabbit liver and horse kidney MTs (previously isolated by SEC and anionic-exchange chromatography) were analyzed under pH selected conditions. In moderately acidic (pH 4.0) and neutral (pH 6–7) media, the complexes of MTs with Cd and Zn retain

**Figure 3** ESI mass spectra taken in the vicinity of the apexes of the RP-LC elution of rabbit liver MT-2. (A) Spectrum obtained without postcolumn acidification.  $M_{r1} = 6804$ ,  $Cd_5Zn_2$ -MT-2a;  $M_{r2} = 6852$ ,  $Cd_6Zn$ -MT-2a;  $M_{r3} = 6898$ ,  $Cd_7$ -MT-2a;  $M_{r4} = 6932$ ,  $Cd_7$ -MT-2c. (B) Spectrum obtained after postcolumn acidification.  $M_{r1} = 6125$ , apo-MT-2a;  $M_{r2} = 6156$ , apo-MT-2c. (Reprinted with permission from Chassaigne H and Lobinski R (1998) Characterization of metallothionein isoforms by reversed-phase high-performance liquid chromatography with online postcolumn acidification and electrospray mass spectrometric detection. *Journal of Chromatography A* 829: 127–136; © Elsevier.)

their conformation in the gas phase and produce ions of intact complexes at the ESI source. In contrast, strong acidic conditions (pH 1.9) cause the loss of Cd and Zn and so the corresponding apo-forms of the protein are obtained. Therefore, when ESI is applied to the sample under neutral pH, the mass spectra of the metallo-subisoforms are obtained. Conversely, under acidic pH the mass spectra of the apo-forms (free ligand) are obtained. As a result, the difference between both mass spectra allows the determination of the stoichiometry of the separated analytes (metallo-subisoforms). In this way, Cd and Zn were speciated in rabbit liver MT-2 (see Figure 3), showing that Cd was mainly bound to MT-2a subisoform ( $M_r = 6125$ ) and MT-2c ( $M_r = 6156$ ). Both subisoforms bind Cd and Zn forming several metal complexes (e.g.,  $Cd_7$ -MT,  $Cd_6$ -Zn-MT,  $Cd_4$ -Zn<sub>3</sub>-MT, etc.).

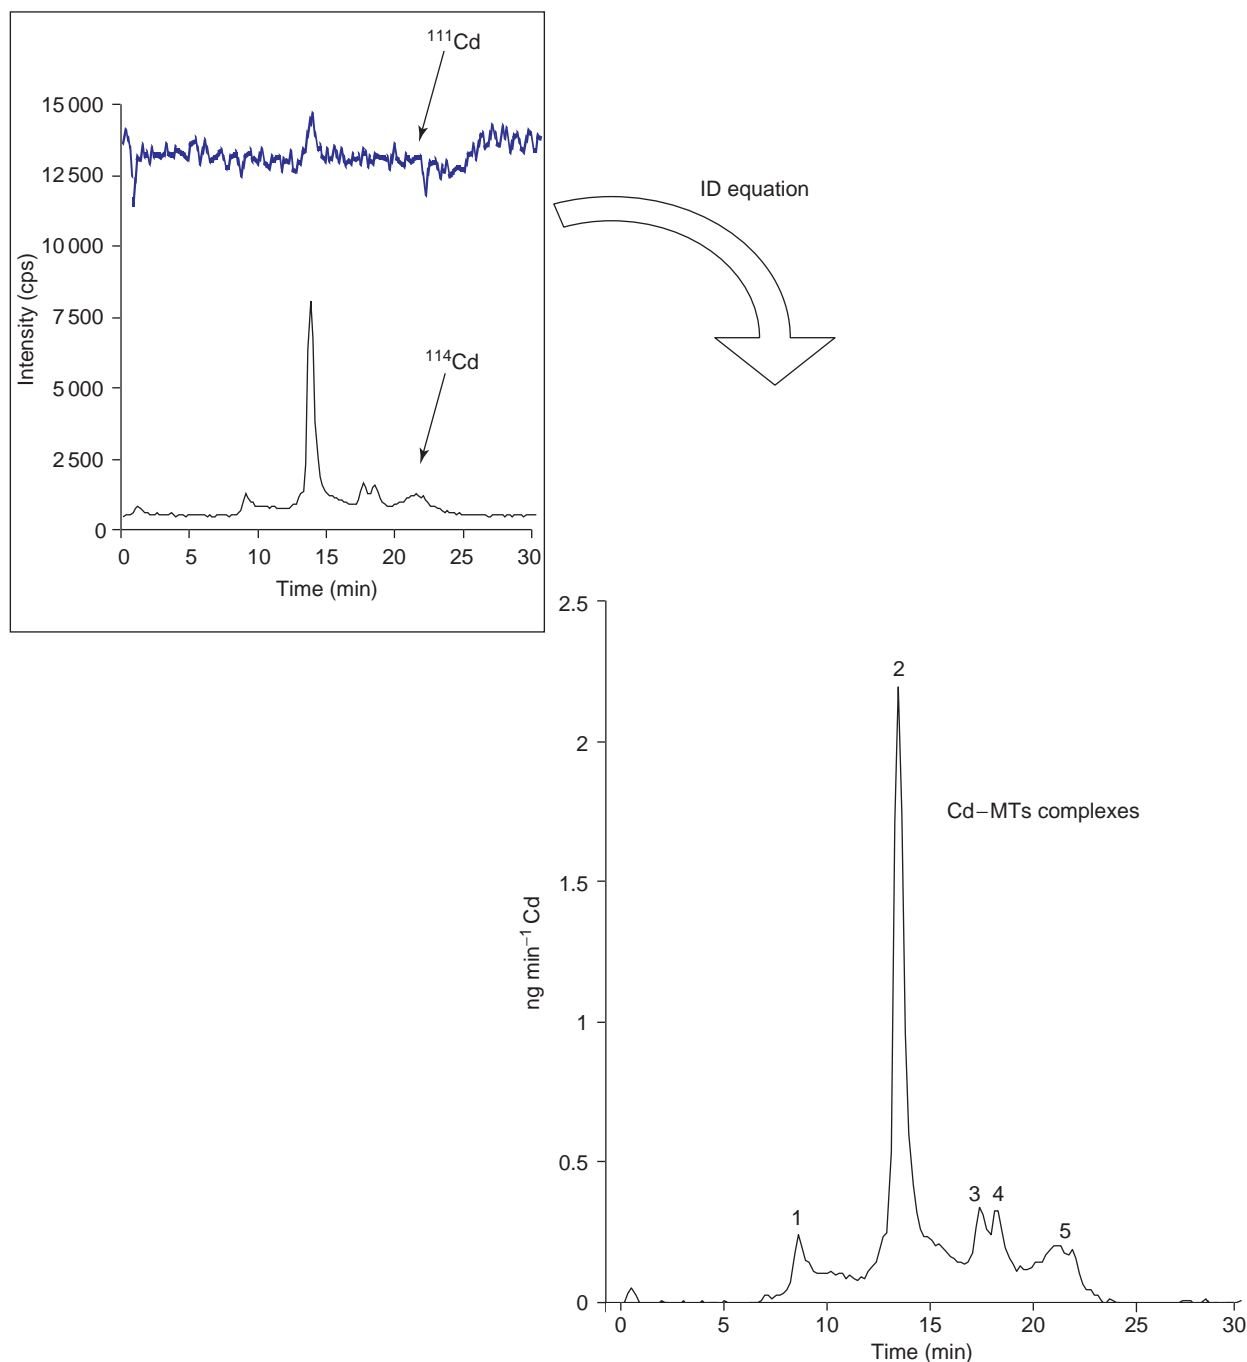

The direct analysis of PC–Cd complexes by ESI-MS/MS from plants extracts is relatively simple and

PC–Cd complexes produced in plants, e.g., in response to metal stress, can be studied.

Hyphenation of CE to ESI-MS seems to be difficult because it requires special coupling interfaces. However, such technology is available at present and, in

fact, some Cd speciation studies have been performed recently.

To conclude this section, it should be pointed out that despite the advantages of using ‘organic’ MS (ESI-MS) for the speciation of Cd in metallated

**Figure 4** Quantification of separated Cd species in fish MTs (real sample) by AE-FPLC–ID-ICP-MS.  $^{111}\text{Cd}$  was used as spike. Inset shows the transformation of intensity signals into mass flow chromatogram (by means of ID equation). The quantification of Cd bound to each metalloproteins (numbered from 1 to 5) could be achieved by this technique. (Rodríguez-Cea A, Fernández de la Campa MR, Blanco González E, Andón B, and Sanz-Medel (2003) Metal speciation analysis in eel (*Anguilla anguilla*) metallothioneins by anionic exchange FPLC-isotope dilution-ICP-MS. *Journal of Analytical Atomic Spectrometry* 18: 1357–1364; reproduced from The Royal Society of Chemistry.)

biocomplexes, there is 100–1000 times lower sensitivity for this detection in comparison to ICP-MS for real sample analysis. This renders molecular MS analysis of MTs or PCs at basal (not induced) levels in real samples yet a rather difficult task.

## Quantification of Cadmium Species by Isotope Dilution ICP-MS

Once a given Cd-bioligand has been identified and its chemical nature established, an accurate and precise determination of such species should be aimed at. The risk of species alteration during the analytical procedures and the relatively few papers published on validation of quantitative speciation results explain that validation of species determinations is still a challenge in real-life situations in speciation analysis. In this sense, isotope dilution (ID) analysis has been accepted as a definitive method for precise and accurate analysis in organic MS for years. This ID concept was extended to trace metals speciation by ICP-MS in environmental samples almost a decade ago. Then, it has been applied to accurate determinations of organotin, organolead, and organomercury compounds. The prerequisite of ID is that the analyte of interest must have at least two stable isotopes. Thus, it is not surprising that this method has also been applied for the quantification of Cd and its species, mainly to quantify the complexes formed between  $\text{Cd}^{2+}$  and MTs.

In ID, the natural isotopic abundance ratio of Cd is altered in the sample by spiking it with an exact and known amount of Cd-enriched isotope (the so-called 'spike', with a different isotopic abundance ratio than natural cadmium). The reference isotope is usually the isotope of highest natural abundance ( $^{114}\text{Cd}$ ), while the spike isotope is one of the lesser abundant natural isotopes (normally  $^{106}\text{Cd}$ ,  $^{116}\text{Cd}$ , or  $^{111}\text{Cd}$ ). As a result of the spiking process, the measurement by ICP-MS of the new isotope ratio (e.g.,  $^{114}\text{Cd}/^{111}\text{Cd}$ ) and its comparison with the natural isotope ratio offers the original Cd concentration in the sample. If the isotope dilution is performed 'online' in an LC- or CZE-ICP-MS experiment, quantification of Cd in each of the isolated species can be accurately achieved by integration of each chromatographic/electrophoretic peak after transformation of the data into 'mass flow' by means of the ID equation.

The quantification of Cd and other metals in MTs offers a great environmental interest in order to understand the role of metals in proteins and the potential use of such metals–MT concentrations as biomarkers of metal pollution. Usually, these kinds of environmental studies involve the analysis of Cd,

Cu, and Zn bound to MTs (such metal–MTs concentrations are interrelated). In this sense, LC-ID-ICP-MS has been applied to the speciation of Cd, Cu, and Zn in liver and kidney of fish under Cd stress. In **Figure 4**, the Cd speciation profile obtained by ID-ICP-MS in fish liver after online separation by anionic-exchange chromatography is illustrated. The ID quantification of Cd in each chromatographic peak provides the metal amount (nanogram) bound to different proteins. As can be seen, the relative amount of Cd (peak area) bound to each protein is considerable, pointing out the importance of Cd speciation studies in investigating bioindicators of environmental contamination.

On the other hand, combination of CE with ID-ICP-MS has also been successfully applied to Cd speciation, but using a double focusing ICP-MS detector. The determination of Cd, Cu, and Zn molar ratios in MTs, using such instruments, which enables the determination of  $^{32}\text{S}$  and  $^{34}\text{S}$  without interferences, has already been described.

### Introduction

Electrochromatography was first introduced in 1939. From its discovery it took a further 50 years to attain its modern form, capillary electrochromatography (CEC). This may sound astounding, but it must be realized that not only was it necessary for the theoretical framework to be developed, but also essential technologies underpinning the very existence of CEC needed to emerge. The first of these technologies was the advent of the fused silica capillary in 1979, spurring the development of capillary gas chromatography, and later of capillary electrophoresis (CE) from the 1980s, followed by CEC in the 1990s. Some of the important developments in CEC are summarized in **Table 1**. An evaluation of published literature in CE and CEC (**Figure 1**) reveals that CEC is a relatively recent analytical separation method and is applied much less frequently than CE.

CEC is a combination of liquid chromatography (LC) and CE, combining the advantages of the presence of a chromatographic stationary phase (as occurs in LC) with the separation efficiency achieved in CE as a result of using an applied voltage to drive the separation. Because CEC is a hybrid method, it is prudent to provide an exact definition of what falls under the category of CEC. CEC can be defined as any separation method performed in a liquid phase in the presence of a chromatographic stationary phase in a capillary column, under application of

voltage longitudinally along the column. This means that capillary methods in which both pressure and voltage are applied can be categorized as CEC.

It should be noted that electrophoretic separations can be performed by utilizing interactions with a pseudostationary phase contained within the electrolyte. This pseudostationary phase is so named because it consists of soluble species (or a suspension of small particles), which actually move with the flowing electrolyte. That is, this phase is not stationary. Typical pseudostationary phases include soluble polymers, colloid, micelles, or even particles of a heterogeneous solid chromatographic stationary phase dispersed in the electrolyte. Separations using pseudostationary phases are sometimes categorized as electrochromatography, based on the argument that chromatographic partitioning in the pseudostationary phase is involved. To make a clear distinction, we will here classify as CEC only those separations involving a true stationary chromatographic phase, while separation systems with pseudostationary phases will be categorized as electrokinetic chromatography and will be covered elsewhere. A further point regarding the nomenclature to be used in this article is that the terms electrolyte (rather than mobile phase) and migration time (rather than retention or elution time) will be used, based on the reasoning that electrochromatography always involves the use of separation voltage and therefore is an electromigration separation method.

### Introduction

Electrochromatography was first introduced in 1939. From its discovery it took a further 50 years to attain its modern form, capillary electrochromatography (CEC). This may sound astounding, but it must be realized that not only was it necessary for the theoretical framework to be developed, but also essential technologies underpinning the very existence of CEC needed to emerge. The first of these technologies was the advent of the fused silica capillary in 1979, spurring the development of capillary gas chromatography, and later of capillary electrophoresis (CE) from the 1980s, followed by CEC in the 1990s. Some of the important developments in CEC are summarized in **Table 1**. An evaluation of published literature in CE and CEC (**Figure 1**) reveals that CEC is a relatively recent analytical separation method and is applied much less frequently than CE.

CEC is a combination of liquid chromatography (LC) and CE, combining the advantages of the presence of a chromatographic stationary phase (as occurs in LC) with the separation efficiency achieved in CE as a result of using an applied voltage to drive the separation. Because CEC is a hybrid method, it is prudent to provide an exact definition of what falls under the category of CEC. CEC can be defined as any separation method performed in a liquid phase in the presence of a chromatographic stationary phase in a capillary column, under application of

voltage longitudinally along the column. This means that capillary methods in which both pressure and voltage are applied can be categorized as CEC.

It should be noted that electrophoretic separations can be performed by utilizing interactions with a pseudostationary phase contained within the electrolyte. This pseudostationary phase is so named because it consists of soluble species (or a suspension of small particles), which actually move with the flowing electrolyte. That is, this phase is not stationary. Typical pseudostationary phases include soluble polymers, colloid, micelles, or even particles of a heterogeneous solid chromatographic stationary phase dispersed in the electrolyte. Separations using pseudostationary phases are sometimes categorized as electrochromatography, based on the argument that chromatographic partitioning in the pseudostationary phase is involved. To make a clear distinction, we will here classify as CEC only those separations involving a true stationary chromatographic phase, while separation systems with pseudostationary phases will be categorized as electrokinetic chromatography and will be covered elsewhere. A further point regarding the nomenclature to be used in this article is that the terms electrolyte (rather than mobile phase) and migration time (rather than retention or elution time) will be used, based on the reasoning that electrochromatography always involves the use of separation voltage and therefore is an electromigration separation method.

### Instrumentation

At its current stage of development, where commercial instrumentation from the major manufacturers is

**Table 1** Some important developments in CEC

Time	Development
1939	Electric field used in LC (Strain HH (1939) Combination of electrophoretic and chromatographic adsorption methods. <i>Journal of American Chemical Society</i> 61: 1292–1293)
1943	Term 'electrochromatography' introduced when discussing paper electrophoresis (Berraz G (1943) Electrocapillary analysis. <i>An. Assoc. Quim. Argent</i> 31: 96–97)
1949	Electric field used in transport of compounds through a gel (Shepard CC and Tiselius A (1949) The chromatography of proteins. The effect of salt concentration and pH on the adsorption of proteins on silica gel. <i>Discuss. Faraday Soc</i> 7: 275–285)
1952	Electric field used in TLC (Mould DL and Synge RLM (1952) Electrokinetic ultrafiltration analysis of polysaccharides. A new approach to the chromatography of large molecules. <i>Analyst</i> 77: 964–970)
1974	Electrochromatography in a packed column of 1 mm ID (Pretorius V, Hopkins BJ, and Schieke JD (1974) Electroosmosis. New concept for high speed liquid chromatography. <i>Journal of Chromatography</i> 99: 23–30)
1979	Fused silica capillary technology (Dandenau RD and Zerenner EH (1979) An investigation of glasses for capillary chromatography. <i>HRC&amp;CC</i> 1: 351–356)
1981	CEC in 170 $\mu$ m ID capillary packed with 10 $\mu$ m particles (Jorgenson JW and Lukacs KD (1981) High-resolution separations based on electrophoresis and electroosmosis. <i>Journal of Chromatography</i> 218: 209–216)
1987	CEC in open-tubular and packed columns (Tsuda T (1987) Electrochromatography using high applied voltage. <i>Analytical Chemistry</i> 59: 521–523)
1987, 1991	CEC with small particles, detailed studies (Knox JH and Grant IH (1987) Miniaturization in pressure and electroendosmotically driven liquid chromatography: some theoretical considerations. <i>Chromatographia</i> 24: 135–143; Knox JH and Grant IH (1991) Electrochromatography in packed tubes using 1.5 to 50 $\mu$ m silica gels and ODS bonded silica gels. <i>Chromatographia</i> 32: 317–328)
1991	Hyphenation with MS (pressurised CEC–CF–FAB–MS) (Verheij ER, Tjaden UR, Niessen WMA, and van der Greef J (1991) Pseudo-electrochromatography–mass spectrometry: a new alternative. <i>Journal of Chromatography</i> 554: 339–349)
1995	Rigid polyacrylamide gel as a CEC stationary phase (Hjertén S, Eaker D, Elenbrink K <i>et al.</i> (1995) <i>Japanese Journal of Electrophoresis</i> 39: 105–???)
1997	Rigid macroporous polybutylmetacrylate as a monolithic CEC stationary phase (Peters EC, Petro M, Svec F, and Fréchet JMJ (1997) <i>Analytical Chemistry</i> 69: 3646–3649)

**Figure 1** Numbers of publications for CEC and CE from 1985 to 2002. Source: Chemical Abstracts database accessed through SciFinder Scholar, searched for 'capillary electrophoresis – concept', and 'capillary electrochromatography – concept'.

marketed as hybrid CE/CEC instruments, CEC has very strong similarities to CE in its instrumental requirements. However, there are two main differences between the instrumental implementation of CEC and CE. The first is the presence of some form of

stationary phase inside the separation capillary column (the capillaries used for the CEC columns are usually the same fused silica capillaries as used in CE) and the second is the frequent requirement for overpressure to be applied onto the electrolyte

**Figure 2** Schematic representation of a CEC instrument.

reservoirs (at both injection and detection ends of the capillary) during the separation to help prevent bubble formation. A schematic representation of such a CEC instrument is shown in **Figure 2**. It should be noted that the current situation with commercial CE instruments being used for CEC does not access the full potential of CEC, especially the use of gradient elution analysis. A  $\mu$ -LC/nano-LC pump capable of pumping the electrolyte through the column at defined flow rates would bring significant advantages for usage of pressure-assisted CEC, flushing, and conditioning of CEC columns, or for loading of sample solution onto the CEC column. Therefore, the need for a hybrid gradient  $\mu$ -LC/nano-LC-CEC-CE instrument seems to be clearly evident. Such instruments have been constructed by several research groups but have not been introduced by any of the major commercial CE/CEC instrumentation manufacturers.

### Sample Introduction

As in CE, hydrodynamic or electrokinetic (electromigration) sampling is used, i.e., by applied pressure or voltage.

Electrokinetic sample introduction is known to be matrix dependent; therefore, hydrodynamic sample introduction is normally preferred. If electromigration injection is to be employed, matrix effects should be investigated and standard addition calibration rather than external standard calibration should be used.

### CEC Columns

The CEC columns have similarities to capillary columns used in  $\mu$ -LC/nano-LC, but there are several important differences. First, in CEC, the separation current resulting from the applied separation potential produces heat that must be dissipated effectively, otherwise bubble formation or even drying out of

**Figure 3** Modes of CEC with respect to the column type. From left to right illustrated schematically are: open-tubular columns, packed columns, and monolithic columns.

portions of the CEC column bed can result. Therefore, the inner diameter of CEC fused silica capillary columns usually does not exceed 100  $\mu$ m and an efficient capillary cooling system is essential. Additionally, electrolyte vials are often overpressurized (using helium or nitrogen at  $\sim 10$  bar) to further prevent bubble formation. Second, the nature of the electroosmotic flow (EOF) driving the flow of electrolyte through the CEC column allows the use of very small packing particles (even with diameters  $< 1 \mu$ m). There are three main types of CEC columns, namely open-tubular (OT) columns, packed columns, and monolithic columns, as illustrated schematically in **Figure 3**. These modes of CEC are described in more detail in the section 'Modes of CEC'.

### Detection

The most common detection method used in CEC is direct photometric detection, which offers the same advantages and disadvantages as its use in CE. Its strengths include simplicity, robustness, and widespread applicability to most analytes, while its lack of structural information for identification of analytes and moderate detection sensitivity are its drawbacks. Using direct photometric detection, a direct comparison of detection sensitivity between CEC and high-performance liquid chromatography (HPLC) for the same set of analytes yielded a 100-fold poorer method sensitivity for CEC, which is not surprising given that a typical path length in CEC using on-capillary detection (50–100  $\mu$ m) is about two orders of magnitude smaller than a typical detector cell path length in HPLC (5–10 mm).

Other detection methods can be applied to CEC. Indirect spectrophotometric detection methods are commonly used for ultraviolet (UV)-transparent ionic analytes (such as inorganic ions) in CE, but indirect detection in CEC tends to suffer from unstable baselines, caused by adsorption of the indirect detection probe onto the CEC ion-exchange stationary phases (SP). Fluorimetric detection is a very sensitive and robust method, but is limited to a relatively small

number of analytes. Electrochemical detection methods, such as conductometry, amperometry, and potentiometry, can be utilized in a manner similar to CE, and the same principles, strengths, and weaknesses apply. Amperometric detection would be the detection method of choice for analytes that can be easily reduced or oxidized, but the range of suitable analytes is rather limited. On-capillary contactless conductivity detection can be used for ionic analytes exhibiting different mobility to that of the electrolyte coion, but again its performance in CEC tends to be inferior compared to CE.

The lack of reliably performing indirect detection in CEC, and in fact of any reliable, sensitive, and universal detection method, makes the need for an alternative universal detection method even more obvious than in CE. Various mass spectrometric (MS) detection methods hyphenated with the CEC separation column can fulfill this task. In the future, MS detection methods are likely to further grow in popularity, especially with continuing improvements in the MS instrumentation and its affordability.

## Principles and Practical Considerations

### Conductivity of CEC Columns

The conductivity of the stationary phases in CEC is considered negligible, as is the contribution of EOF to the overall conductivity through a CEC column. Therefore, under typical conditions it is solely the electrolyte in the pores of the CEC column that is responsible for conducting the current. Unlike in CE, where the conductivity through the capillary filled with electrolyte is simply given by the conductivity of the electrolyte filling the whole cross-section of the capillary, the conductivity of a CEC column will be considerably smaller due to the presence of nonconductive packing in the CEC column. The 'conductivity ratio',  $\Phi$ , can be defined as the ratio of the conductivities of a CEC capillary column and of an open capillary of same dimensions. Using the Boyack–Giddings equation,  $\Phi$  can be related to the interstitial porosity of the packing and its morphological characteristics:

$$\Phi = \frac{\sigma_{\text{packed}}}{\sigma_{\text{open}}} = \varepsilon_i O T^{-2} \quad [1]$$

where  $\sigma_{\text{packed}}$  is the conductivity of the CEC column,  $\sigma_{\text{open}}$  the conductivity of the CE open capillary,  $\varepsilon_i$  the interstitial porosity,  $O$  the constrictive factor, and  $T$  the tortuosity. The last two experimental parameters are associated with inconsistent channel cross-sectional area and with the fact that the channels and

the electric field vectors generally do not run parallel. It should be noted that interstitial porosity in LC is termed 'total porosity' and is simply the fraction of the void volume relative to the volume of the empty column, thus corresponding to the volume between the particles of the packing plus the volume of all accessible pores. Typical values in HPLC fall in the range 0.25–0.4. The values of conductivity ratios in CEC fall within the range of  $\sim 0.3$ –0.7, with CEC columns packed with pellicular chromatographic particles being at the lower end of the range, followed by typical 300 Å silica packings, and packings of macroporous particles and monolithic packings giving conductivity ratios at the upper end of the range.

The conductivity of the CEC column is also important when considering the profile of heat generation and dissipation that is to be expected along the CEC column. Unlike in CE, where the whole capillary is filled with a homogeneous electrolyte exhibiting a uniform conductivity, such that the electric field and the generated heat will also be uniform along the capillary length, in CEC the conductivity will be different for the open capillary section, the frits, and the column bed (and also can vary along the column bed if it is inhomogeneous). This situation is illustrated in Figure 4 for a hypothetical CEC packed capillary column held between two frits and

**Figure 4** Simulated heat-generation profile calculated along a typical packed CEC capillary column with the packing held between two frits, with an empty capillary section from the detection side frit. Parameters – total capillary length: 0.340 m; CEC column length including frits: 0.237 m; length of inlet and outlet frits: 4 mm; porosity of frits: 0.5; porosity of stationary phase: 0.6; voltage: 20 kV; current: 25  $\mu$ A.

with an open capillary section after the frit on the detection end of the capillary. In this example, the porosity of the frits was somewhat lower than the packed bed (which is a realistic scenario for frits prepared by sintering the same material as in the packed section). The graph clearly shows that the calculated profile of the electric field and the generated heat is nonuniform, and the system is likely to exhibit 'hot-spots' at the frits. This can cause bubble formation with deleterious consequences for the CEC analysis. Apart from overheating, other factors attributed to bubble formation are nonuniform EOF resulting in pressure differences at the interfaces between the different sections of the CEC capillary column and nonuniform surface tension along the CEC capillary column.

### Electroosmotic Flow

The principles of EOF and its role in CEC separations are the same as for CE.

The presence of EOF as the source of flow of the electrolyte through the CEC column has two very profound effects. First, by the nature of the EOF, the pressure difference across the whole CEC column bed is zero. This means that much smaller particle sizes can be used, down to  $\sim 1 \mu\text{m}$  particle diameter, with 3–5  $\mu\text{m}$  particles being used routinely. Second, the plug-like profile of the EOF is responsible for the typical higher separation efficiencies achieved in CEC compared to LC.

EOF arises due to the presence of charges on the inner surface of the capillary wall, and in CEC also on the surface of the CEC stationary phase, which give rise to the presence of a charged double-layer of a fixed (Stern) layer and a mobile, diffuse (Gouy–Chapman) layer. In the presence of an electric field directed longitudinally relative to the charged surfaces (i.e., where high voltage is applied at the ends of the CEC capillary column), the charges in the diffuse layer will move in the electric field along a shear plane between the fixed and diffuse layers, dragging the bulk liquid. Locally at the packing surface, the electroosmotic mobility is expressed by the Smoluchowski equation:

$$\mu_{\text{CEC,local}} = -\frac{\varepsilon\varepsilon_0\zeta}{\eta} \quad [2]$$

where  $\zeta$  is the zeta potential of the surface of the CEC stationary phase,  $\eta$  the viscosity of the electrolyte,  $\varepsilon$  the dielectric constant, and  $\varepsilon_0$  the dielectric constant *in vacuo*.

Alternatively, when expressing the zeta potential as a function of the charge density at the shear surface and of the double-layer thickness, and substituting

for the double-layer thickness from the Debye–Hückel approximation, one arrives at the Hunter equation:

$$\mu_{\text{CEC,local}} = \frac{\sigma[\varepsilon\varepsilon_0RT/2cF^2]^{1/2}}{\eta} \quad [3]$$

where  $\sigma$  is the charge density at the shear surface,  $R$  the gas constant,  $T$  the temperature,  $c$  the electrolyte concentration, and  $F$  the Faraday constant. Importantly, this equation shows that the EOF decreases with electrolyte concentration (in the absence of double-layer overlap which occurs in very narrow channels and/or at low electrolyte concentrations).

An overall (average) electroosmotic mobility over the whole CEC column bed takes into account the conductivity ratio from eqn [1]:

$$\mu_{\text{CEC}} = \mu_{\text{CEC,local}} \left( \frac{\sigma_{\text{packed}}}{\sigma_{\text{open}}} \right) \quad [4]$$

This shows that the EOF in CEC increases with increasing porosity of the stationary phase bed.

Another important conclusion can be drawn from the fact that packing particle diameter does not appear in the equations for EOF in CEC. Unlike in LC, in CEC the packing particle diameter does not exert any direct major influence on the flow of the electrolyte through the CEC column bed. Therefore, smaller packing particles can be used, often below 1  $\mu\text{m}$ . The minimum applicable particle size is limited by double-layer overlap occurring typically in channels below 1  $\mu\text{m}$ . This effect is also important in perfusive packings, which are macroporous packings with pores large enough (usually approaching 1000 Å or larger) to support perfusive (intraparticulate) EOF.

Not only is the EOF a fairly complex phenomenon in itself, but another complexity arises from the fact that surfaces inside the CEC column can exhibit substantially different EOF (at the capillary wall surface, frit surface, SP surface, or at different points of the stationary phase, such as in different pores), and that the surfaces inside the CEC column follow a complex morphology. These factors can lead to very complex flow patterns inside the CEC column. The main contributions to the bulk flow through the column are the EOF-induced flow through the chromatographic bed (and the frits, if present), and the EOF of the capillary wall in the open section. The EOF through the chromatographic bed can act as an 'EOF pump', inducing pressure-driven flow in the open capillary section, since the flow resulting from the CEC bed will be generally different to the EOF in the open section.

### Efficiency

The smaller particle size used in CEC compared to LC, together with the beneficial effects of EOF on the 'A' and 'C' terms of the van Deemter equation, result in separation efficiencies for CEC which exceed those of LC by a factor of  $\sim 2$ – $5$ . Efficiencies of  $\sim 200\,000$ – $500\,000$  theoretical plates per meter are typical for CEC. The two main beneficial effects of EOF, namely a more uniform flow profile across the column bed, and an enhanced mass transfer, are explained in more detail in the paragraphs below.

In the CEC bed, the linear flow velocity of the EOF through channels of different diameters will be independent of the channel diameter, provided the channel is wide enough to avoid double-layer overlap (under typical experimental conditions the critical channel diameter is  $\sim 0.1\,\mu\text{m}$ ). This significantly reduces (usually by a factor of  $2$ – $5$  times) the 'A' term in the van Deemter equation, also referred to as 'Eddy diffusion', and is primarily responsible for the significantly higher separation efficiencies achieved on a capillary column operated in the CEC mode compared to the same column operated in LC mode (pressure-driven).

Another effect contributing to higher separation efficiencies in CEC compared to LC is thought to arise from improved mass transfer (the 'C' term in the van Deemter equation, which is usually decreased by a factor of  $1.5$ – $5$  times). This results from mixing effects of vortices created by nonuniform EOF of the pore wall and physical obstructions in the flow path such as narrowing of the pore or even the presence of dead-end pores.

### Retention and Selectivity

The overall speed with which an analyte moves through the CEC column bed is given by a combination of both electrophoretic (CE) and chromatographic (LC) factors. Rathore and Horvath defined electrochromatographic retention factor as

$$k_{\text{CEC}} = k_{\text{LC}} + k_{\text{LC}}k_{\text{CE}} + k_{\text{CE}} \quad [5]$$

where  $k_{\text{LC}}$  is chromatographic retention factor and  $k_{\text{CE}}$  the electrophoretic velocity factor defined as a ratio of electrophoretic mobility of an analyte to electroosmotic mobility. It should be noted that for a neutral solute,  $k_{\text{CE}} = 0$  and  $k_{\text{CEC}}$  will revert to an expression for chromatographic retention factor. The disadvantage of this approach is that the electrochromatographic retention factor  $k_{\text{CEC}}$  cannot be determined from CEC data alone and an independent measurement of the CE contribution is needed. Therefore, for practical purposes, the position of

the analyte peak in the CEC electrochromatogram is characterized using a dimensionless retention factor, often expressed as

$$k'_{\text{CEC}} = \frac{t_{\text{m}} - t_0}{t_0} \quad [6]$$

where  $t_{\text{m}}$  and  $t_0$  are the migration times of the analyte and an inert neutral marker in a CEC column. It must be stressed that this retention factor is devoid of any insight into the mechanism of retention. Its disadvantage is that for cationic analytes migrating faster than the EOF it is possible that  $t_{\text{m}} < t_0$  and in that case  $k'_{\text{CEC}} < 0$  which might appear to be irrational by comparison with the chromatographic retention factor.

As described by eqn [5], the overall separation selectivity in CEC will be composed by contributions from both the LC and the CE mechanisms. Especially when developing a CEC method based on an existing LC method, it is important to realize that the CEC separation selectivity will always differ to some degree from that of the parent LC method. For uncharged analytes (usually separated in the reversed-phase CEC mode), the CEC separation selectivity should in principle closely resemble that of the LC separation using the same packing. However, in practice CEC retention factors tend to be larger by  $\sim 20\%$  compared to  $\mu$ -LC under the same conditions, and this discrepancy is attributed to possible influences of the electric field in CEC on the chromatographic stationary phase and the distribution constants of the analytes. Even more importantly, for any charged analyte, the overall CEC separation selectivity will also include a CE component based on the migration of the charged analytes. Thus, for instance, in a CEC separation on a reversed-phase stationary phase conducted in the usual arrangement with positive voltage polarity at the injection end and cathodic EOF driving the electrolyte toward the detector side, in the absence of ion-exchange interactions between the analyte and the stationary phase, the migration time of any cationic analyte will be smaller compared to the LC mode, and that of any anionic analyte will be larger.

### Modes of CEC

CEC columns can be categorized with respect to the type of stationary phase as OT columns, packed columns, and monolithic columns, as illustrated in Figure 3. It should be noted that a particular CEC stationary phase type can be realized in a fused silica capillary, or in a channel of a microfluidic chip.

## Open-Tubular Columns

OT columns in CEC are analogous to OT columns in gas chromatography. A significant practical advantage of OT columns, especially compared to packed column CEC, is the ease with which the electrolyte can be flushed through the OT column using a moderate applied pressure.

OT CEC columns are relatively easy to prepare, with the stationary phase being bound onto the capillary wall using well-established procedures. For example, reversed-phase OT stationary phases can be formed by attaching hydrophobic C18 groups using the same chemical reactions as applied in the synthesis of reversed-phase LC stationary phases. The principal problem of OT columns is the relatively low ratio of stationary to mobile phase, resulting in low retention and capacity of the OT columns. This can be partially addressed by increasing the amount of stationary phase attached onto the capillary wall, usually by etching the capillary wall before attaching the stationary phase. The limit of this approach is the danger of decreasing separation efficiency by increasing the resistance to mass transfer (the 'C' term in the van Deemter equation). Another problem is the necessarily small capillary diameter required because of the low diffusion coefficients of analytes in liquids. These factors cause the capillary diameters of the OT columns to be generally smaller compared to packed and monolithic CEC columns, with capillary diameters of 25  $\mu\text{m}$  ID or less being typical. As a result, this places demands on detection methods, with the

sensitivity of photometric detection being typically unsatisfactory for these small ID columns.

## Packed Columns

Packed column CEC is a logical extension of previous research in  $\mu\text{-LC}$ /nano-LC systems conducted through the 1970s and the 1980s. The most common procedure for preparation of packed CEC columns is slurry packing under high pressure. A typical example of this procedure is shown in **Figure 5**, which illustrates the steps required to pack a bed of polymeric stationary phase, retained by two frits composed of silica. In the top frame, an aqueous slurry of silica particles is pressure-packed into the end-section of the column where the detection end frit is to be made. The frit is then made by sintering a short portion of the silica packing with a heating filament. The unsintered silica packing remaining on both sides of the formed frit is then flushed out of the capillary. A slurry of the desired chromatographic packing (in this example a polymer-based packing material) is then packed from the injection end of the column until only a few millimeters of unpacked capillary remain. This portion of the capillary is then packed with more of the silica packing and the injection end frit is made using the same sintering procedure as for the detection end frit. Finally the capillary is cut such that the injection end frit forms the front (injection end) of the CEC column. Other CEC column packing procedures have been developed for special cases, such as electrokinetic packing

**Figure 5** Packing procedure for CEC columns with sintered silica frits and a polymer particulate packing placed between the frits. See the text for explanation. (Reproduced with permission from Hilder EF (2000) Ph.D. thesis, University of Tasmania.)

for packing CEC sections of a channel on a micro-chip.

Probably the greatest advantage of packed CEC columns is the fact that a wealth of existing LC stationary phases can be used, with reversed-phase materials being the most commonly applied, followed by ion-exchange stationary phases. It could be argued that the very well-defined properties and known selectivity of these stationary phases should make method development easier in CEC. However, two factors that complicate the translation of an LC method into the CEC format must be kept in mind. First, as discussed earlier, the CEC separation selectivity for both uncharged and even more for charged analytes will differ to that of  $\mu$ -LC/nano-LC under identical conditions. Second, specialty CEC stationary phases which differ from typical LC stationary phases are often used, for instance those containing sulfonic acid groups which remain fully ionized over the available pH range and will therefore support a strong and pH-independent EOF through the CEC column bed. An example of this type of stationary phase is a reversed-phase material derivatized with alkylsulfonate chains, or with a mixture of alkyl and alkylsulfonate chains.

The miniaturization of the packed columns and especially of the frits makes the preparation of packed CEC columns highly technologically demanding. The columns are difficult to reproduce in terms of parameters such as the EOF, and they are prone to breakage, frit failure, blockage, and the formation of voids. Despite concentrated efforts of many research teams into various alternative frit making and column packing procedures, these problems have not been addressed satisfactorily, leaving an acute demand for an alternative column technology. This demand seems to have been satisfied by the advent of monolithic capillary columns, which are described in the following section. From this perspective, packed columns have been largely replaced by the monolithic capillary columns. Some limited use of packed columns in the future will probably be justified in cases where a specific existing chromatographic stationary phase packing has to be used because of its particular chromatographic properties.

### Monolithic Columns

Monolithic, or continuous bed, columns for LC and CEC are relatively new, but the combination of high capacity, very low pressure resistance, simple *in situ* preparation procedures, and no requirement for frits has made them a very popular choice both in LC and in CEC.

Monolithic CEC columns can be formed from organic porous polymeric monoliths or porous silica sol-gel monoliths. Other monolithic CEC column types, such as immobilized particles, have also been demonstrated but have not shown the potential of the first two types. The monolithic stationary phases are created *in situ* by polymerization reactions under controlled conditions, such that a porous bed is created.

Silica monoliths are prepared by sol-gel technology using hydrolysis and polycondensation reactions. Functionalities for hydrophobic interactions with analytes can be introduced in a subsequent treatment of the bed with alkylsilanes, or by introducing hydrophobic functionalities in the monomer mixture (Figure 6).

For organic polymers, a mixture of monomers and an organic solvent acting as a porogen is polymerized using free radical UV-light or thermal initiation. Clearly, these procedures have to be optimized carefully, but once that is done, the process is claimed to be reproducible. The chromatographic selectivity of the resultant monolith depends on the monomers used and can be altered by attachment of additional functionalities, such as alkyl chains for hydrophobic interactions or charged groups for ion-exchange interactions. Typical polymers used are acrylate, methacrylate, polystyrene, and various copolymers. EOF is provided by charged groups, usually sulfonate

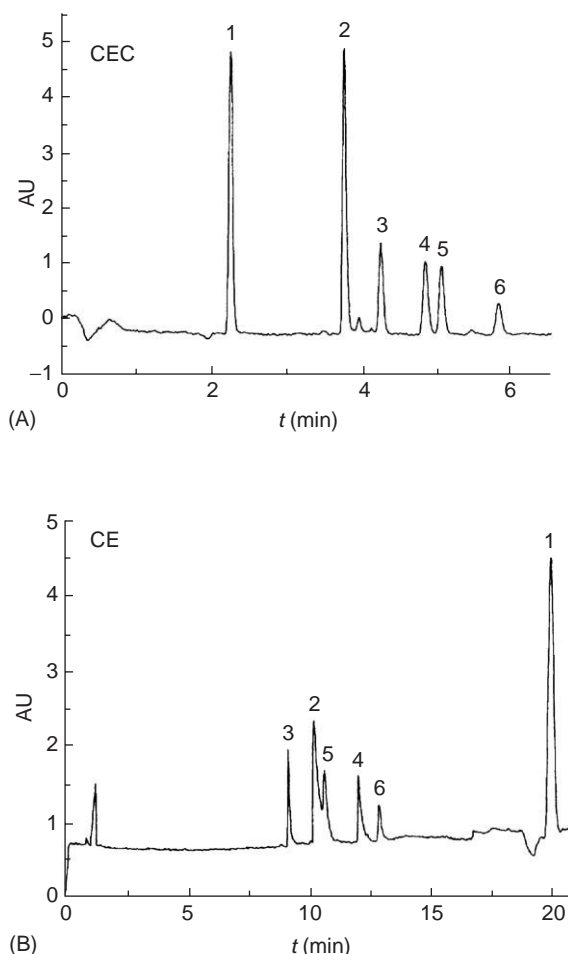

**Figure 6** SEM of silica monolithic CEC column inside a fused silica capillary. Conditions – fused silica ID: 75  $\mu$ m; the monolith was prepared by the procedure described by Ishizuka N, Kobayashi H, Minakuchi H, *et al.* (2002) *Journal of Chromatography A* 960: 85–96. (Courtesy of Mr. J. Hutchinson.)

groups for cathodic EOF, or quaternary ammonium groups for anodic EOF. A special category of stationary phases is molecular imprinted polymers used for enantioselective separations, where one isomer is 'imprinted' into the stationary phase during its polymerization, thus providing molecular-size cavities where this isomer will be specifically retained. A remarkably powerful technique when using reactions initiated by UV-light is photopatterning, where different sections of the capillary are covered with a mask, and the uncovered section is exposed to UV-light to induce photopolymerization reactions. Different sections of the CEC capillary column can therefore be filled with monolithic materials having different functionalities. This can provide powerful separation tools especially in the microchip format.

## Application Potential

During the past decade many sample types have been investigated using CEC in order to assess its analytical potential. Because CEC carries an additional degree of difficulty compared especially to CE (namely the presence of a stationary phase), it has been suggested that there should be a clear advantage of CEC, such as higher separation efficiency or shorter analysis time, to justify why CEC should be used in preference to CE. The number of cases where such an advantage could be demonstrated clearly would be small. However, taking into account all the advantages offered by the presence of a chromatographic stationary phase (chromatographic gradient separation, sample preconcentration from volumes beyond one capillary volume, and chromatographic peak focusing), it should be recognized that CEC has very significant analytical application potential. It is to be expected that monolithic column technology will prove effective in providing CEC methods, which are competitive with the main alternatives – CE and  $\mu$ -LC/nano-LC.

The examples of CEC separations shown in Figures 7–9 arise from the above considerations: most importantly, in all cases they are efficient and rapid separations – Figure 7 in 6 min and Figures 8 and 9 in less than 1 min. Figure 7 shows a separation of several peptides on a strong cation-exchange stationary phase in the CEC mode (A), which is superior in both separation efficiency and separation time to CE (B). It would be fair to point out that use of a coated capillary containing sulfonate groups in the CE separation would provide a stronger EOF at the low pH used (3.0) and the separation would be faster, but peaks 2 and 5 then would not be separated.

**Figure 7** Separation of peptides by ion-exchange CEC (A) and by CE (B). Conditions: (A) 75  $\mu$ m ID capillary column, total length 0.310 m, column bed 0.010 m packed with Spherisorb-SCX 5  $\mu$ m; temperature, 20°C; voltage, 15 kV; electrolyte, 60% acetonitrile in 30 mmol L<sup>-1</sup> potassium phosphate buffer (pH 3.0); overpressure in both vials, 6.9 bar; detection, photometric at 200 nm; injection, electrokinetic, 5 kV for 10 s; (B) 50  $\mu$ m ID capillary, total length 0.502 m, length to detector 0.400 m; voltage, 25 kV; injection, hydrodynamic, 0.035 bar for 5 s. Peaks: 1 = benzylalcohol; 2 = Gly-Thr; 3 = Gly-Ala-Gly; 4 = Glu-Glu; 5 = Gly-Gly-Asn-Ala; 6 = Glu-Glu-Glu. (Reproduced with permission from Ye M, Zou H, Liu Z, and Ni J (2000) Separation of peptides by strong cation-exchange capillary electrochromatography. *Journal of Chromatography A* 869: 385–394.)

Figure 8 again shows a separation of several peptides on a cation-exchange stationary phase, in this case a monolithic material. A short column bed, a high separation voltage, and also probably a high EOF contribute to a short separation time of less than 1 min. Figure 9 shows a reversed-phase separation of labeled peptides on a monolith used in a microchip format, with separation time again less than 1 min. The last two examples illustrate the potential of monolithic CEC columns and of CEC in the microchip format.

**Figure 8** Separation of peptides using monolithic capillary grafted with 2-acrylamido-2-methyl-1-propanesulfonic acid. Conditions: 100  $\mu\text{m}$  ID capillary column, total length 0.345 m, monolith 0.085 m, 30 s grafting; temperature, 60°C; voltage, 15 kV; electrolyte, 100  $\text{mmol l}^{-1}$  NaCl solution in 10  $\text{mmol l}^{-1}$  phosphate buffer, pH 6.0; overpressure in both vials, 0.8 MPa; detection, photometric at 214 nm; injection, pressure-driven, 0.8 MPa for 0.05 min; sample, 0.1  $\text{mg ml}^{-1}$ . Peaks: S = system peak; 1 = Gly-Tyr; 2 = Val-Tyr-Val; 3 = methionine enkephalin; 4 = Ileucine enkephalin. ### Separation Strategies and Experimental Variables

In a typical CEC arrangement, a positive separation voltage is applied to the inlet of a CEC column exhibiting a cathodic EOF, which means that the EOF flows toward the detector. Any unretained cation (exhibiting no interaction with the stationary phase) will migrate before the EOF, and any unretained anion will migrate after the EOF. Because of the experimental similarity of CEC to CE, the major experimental parameters that can be optimized are the electrolyte composition, separation voltage, and temperature. Further parameters, which are specific to CEC are the stationary phase and dimensions of the column.

In a major difference to LC, where the column temperature can be varied over a wide range from below room temperature to close to the boiling point of the most volatile component of the mobile phase, in CEC the column temperature has to be kept low (close to room temperature or below) to minimize the problems associated with heat dissipation (bubble formation). As the EOF exhibits a linear dependence on the separation voltage, the separation voltage is normally kept at the maximum value determined by the avoidance of column overheating. Typically, this maximum voltage available is usually  $\pm 30\,000\text{ V}$ .

**Figure 9** Separation of NDA labeled peptides by reversed-phase CEC in a microchip with negatively charged lauryl acrylate monolithic stationary phase. Conditions: glass microchip, channels 40  $\mu\text{m}$  deep and 120  $\mu\text{m}$  wide, offset double-T design, main channel length 70 mm, length from the junction to waste 60 mm; stationary phase, porous acrylate monolith containing sulfonic groups, all the channels were filled with the monolith to avoid EOF mismatch; voltage, 5 kV (field strength 770  $\text{V cm}^{-1}$ ); electrolyte, 30:70, acetonitrile/25  $\text{mmol l}^{-1}$  borate, pH 8.2, containing 10  $\text{mmol l}^{-1}$  octane sulfonate; detection, fluorimetric (LIF) using 413 nm line of Kr ion laser, at  $\sim 50\text{ mm}$  from the junction; sample, peptides were labeled with naphthalene-2,3-dicarboxaldehyde (NDA). Peaks: 1 = papain inhibitor, 2 = proctolin, 3 = Opioid peptide ( $\alpha$ -casein fragment 90–95), 4 = Ileangiotensin III, 5 = angiotensin III, and 6 = GGG. (Reproduced with permission from Throckmorton DJ, Shepodd TJ, and Singh AK (2002) Electrochromatography in microchips: reversed-phase separation of peptides and amino acids using photopatterned rigid polymer monoliths. *Analytical Chemistry* 74: 784–789.)

Once the column type and stationary phase have been chosen, and the column temperature and separation voltage determined as explained above, the remaining operational parameters that have to be selected relate to electrolyte composition and include electrolyte concentration (ionic strength), pH, organic solvent type and content, and various additives. As in LC and CE, control of the composition of the electrolyte is the most powerful and straightforward tool for governing separation selectivity. As for CE, increasing ionic strength will decrease the EOF. However, unlike in CE, very small channels (less than 1  $\mu\text{m}$ ) are often present in a CEC column, so that double-layer overlap may come into effect especially in low ionic strength electrolytes (see the section ‘Electroosmotic flow’). In such cases, an opposite dependence of EOF on the ionic strength

can be seen. Therefore, the best overall performance of a CEC column in terms of both maximal EOF and separation efficiency can usually be achieved at moderate electrolyte concentrations, usually in the range between 10 and 50 mol l<sup>-1</sup>.

The choice of pH will be dependent primarily on the acid–base properties of the analytes and the charge they acquire at a given pH. Usage of CEC stationary phases containing permanently charged functional groups is helpful in optimizing the pH because the EOF will be relatively independent of pH, so the electrolyte pH can be varied in order to achieve the desired charges on the analytes. The choice of organic solvent again relates to principles well known from LC, for example, in reversed-phase separations where the organic solvent content governs the chromatographic interaction with the stationary phase. The content of organic solvent in the electrolyte will also influence the EOF, the heat generated in the column, and the magnitude of the sample focusing effect upon sample injection. However, these effects can be fairly complex and are beyond the scope of this article. This also applies to the optimization of any other parameters, such as the use of other electrolyte additives, for example, surfactants, enantioselective ligands, etc.

## CEC Used for Sample Preconcentration

In terms of the analytical potential of CEC for real samples, one of the biggest potential advantage of CEC is the presence of a chromatographic stationary phase. This can be highly beneficial for applying sample preconcentration and cleanup and peak focusing on the stationary phase. It has to be noted that the sample preconcentration and cleanup step can be performed in the LC mode since pressure-driven flow allows these operations to be performed at greater speed than flow driven by EOF. As a result of the fact that CEC is a relatively young method, sample preconcentration methods have yet to be fully applied and developed. Monolithic columns again seem to be ideally suited for this purpose as they combine a high sample capacity with high porosity, low pressure resistance, and low resistance to mass transfer, consequently allowing rapid sample preconcentration.

## CEC in Microfluidic Chip Format

The concept of micrototal analytical systems ( $\mu$ TAS) in the late 1980s and the development of the microfluidic chip (also called a microchip) from the early 1990s presented one of the most dynamic and exciting

developments in analytical chemistry. Separation methods realized in the chip format have so far concentrated mainly on CE, as voltage-driven microchip devices are instrumentally more simple than pressure-driven devices containing pumps, valves, etc. Therefore, microchip CEC is preferable to microchip LC. However, the development of CEC on microchips has been hampered by the practical difficulties encountered in packing a CEC column in a microchip. The development of monolithic CEC column technology has provided a viable alternative to conventional packing methods and it can be expected that CEC on microchips using monolithic columns will develop into a powerful separation technique.

## Emerging Instrumentation

There is a need for commercial hybrid capillary-LC/CEC/CE instrument equipped with pumps and gradient solvent delivery. Such an instrument could provide essential sample cleanup and preconcentration capabilities by loading samples under pressure onto a monolithic adsorbent. The CEC mode could then be used for focusing and separation of the analytes and the combination of these processes would provide greater analytical potential than LC or CEC used alone. It has been already demonstrated that a monolithic capillary column can be quantitatively loaded with sample and flushed using extremely high flow rates translating to a linear flow velocity of  $\sim 50 \text{ mm s}^{-1}$ .

Monolithic technology is the best approach for CEC columns, and in fact is the only workable technology to date for CEC on a microchip. Therefore, it seems likely that monolithic stationary phases will be used widely in CEC in general, and more or less exclusively in CEC on microchips. The reason for the success of the monolithic technology is not only that the monoliths are relatively easy to prepare, but especially their low pressure resistance and fast mass transfer make them well-suited for rapid separations. The use of photopolymerization and patterning of different sections of the channel with masks, leading to sections with different stationary phase chemistries, hold great promise for real-world applications to the analysis of difficult samples, where sample preconcentration, cleanup, and separation steps are performed sequentially in two or more different sections of a CEC microchip. Microchip technology also has great potential as a platform for the development of multidimensional separations, combining, for example, LC–CEC, CEC–CE, etc.

Detection techniques are probably the weakest point of the current CEC technology and further

developments in this area are necessary, especially aiming at increased detection sensitivity. Hyphenation of CEC with mass spectrometry may become routine when simpler, smaller and more affordable mass spectrometers become available. Similarly, in inorganic analysis and element speciation, routine use of hyphenation with inductively coupled plasma mass spectrometers would be logical.

## Introduction

Capillary electrophoresis (CE) is an example of a technique that was conceptualized before its time. The technology needed to fully realize the potential

of this technique was not available when Hjerten first demonstrated inorganic ion and protein separations in 1–3 mm quartz tubes in 1967. Hjerten was able to demonstrate that separations were possible in narrow tubes, but there was no reliable source of the submillimeter inner diameter (ID) fused silica capillary that was necessary to realize the full advantages of the technique. Even if there was, detector technology had not evolved to the point where the miniscule amounts of analyte present in nanoliter detection volumes could be measured. It was not until the early 1980s that conditions were right for CE to become a mainstream analytical technique.

Procedures for the production of large quantities of fused silica capillaries were developed to fill the growing demand for capillary gas chromatography columns. The advent of laser induced fluorescence (LIF) and electrochemical (EC) detectors provided the high mass sensitivity necessary for detection in nanoliter volumes. Jorgenson and Lucas published several key papers on modern CE in 1981. Since then CE has experienced exponential growth to the point where there are well over 2000 articles published annually involving CE.

## Instrumental Overview

Figure 1 shows a schematic of a typical CE instrument. A length of fused silica capillary (typically 20–50 cm) filled with separation buffer extends between two reservoirs. To perform a separation the inlet of the separation capillary is moved to the sample for injection. The inlet is returned to the separation buffer reservoir after a volume ( $\sim 20$ – $50$  nL) of sample has been introduced. An electric potential ( $\sim 10$ – $30$  kV) is applied between the two buffer reservoirs. Analytes migrate through the capillary according to their electrophoretic mobility and the electroosmotic flow (EOF). Analytes are detected either on or off column, depending on the particular detector. Separations with efficiencies of 100 000–150 000 plates and analysis times of 10–20 min are typical.

## The Capillary

The capillary is the central component of the CE instrument. Many of the technical advantages as well

as limitations of CE are due to the unique aspects of performing electrophoresis in narrow tubes. Fused silica capillaries dominate modern capillary electrophoresis. Typical dimensions are 5–150  $\mu\text{m}$  ID and 150–360  $\mu\text{m}$  outer diameter (OD), with 50–100  $\mu\text{m}$  ID and 360  $\mu\text{m}$  OD being most common.

There are two major advantages to performing electrophoresis in capillaries. The first is heat generation (referred to as Joule heating) and dissipation. The electric field in slab gel electrophoresis is typically limited to  $\sim 15$ – $40$   $\text{V cm}^{-1}$ . At higher fields, enough heat may be generated to melt the gel. Although gels are not necessary in CE, excess heat generation leads to temperature, and therefore viscosity, gradients across the diameter of the capillary. The analyte near the center of the capillary experiences a lower viscosity and travels faster than the analyte near the capillary walls. This mobility gradient across the diameter of the capillary contributes to peak broadening, degrading the separation.

The heat generated during electrophoresis is similar to any common resistive element and can be described according to

$$\frac{\partial H}{\partial H} = \frac{IV}{LA} \quad [1]$$

where  $I$  is the current,  $V$  the applied voltage,  $L$  the length of the capillary, and  $A$  the cross-sectional area of the capillary. The heat dissipation is proportional to the surface area, not the volume of the capillary. If the diameter of the capillary is increased, the heat generated increases faster than the ability of the capillary to dissipate this heat, giving rise to a

**Figure 1** Schematic of a CE instrument.

**Table 1** Effect of capillary diameter on Joule heating<sup>a</sup>

Capillary diameter ( $\mu\text{m}$ )	Cross-sectional area ( $\text{m}^2$ )	Current ( $\mu\text{A}$ )	$\Delta T(^{\circ}\text{C})$
10	$7.85 \times 10^{-11}$	3	0.00054
25	$4.91 \times 10^{-10}$	19	0.021
50	$1.96 \times 10^{-9}$	75	0.34
75	$4.42 \times 10^{-9}$	169	1.7
100	$7.85 \times 10^{-9}$	300	5.4
150	$1.77 \times 10^{-8}$	675	27

<sup>a</sup>Voltage = 30 kV,  $K = 1 \times 10^{-9} \text{ m}^2 \text{ J}^{\circ}\text{C}$ .

temperature gradient across the capillary. The difference in temperature between the center and inner wall of the capillary ( $\Delta T$ ) is given by

$$\Delta T = 0.24 \frac{Wr^2}{4K} \quad [2]$$

where  $W$  is the power,  $r$  is the radius of the capillary, and  $K$  is the thermal conductivity of the buffer, capillary wall, and polyimide coating.

As shown in **Table 1**, the effect of Joule heating decreases drastically as capillary diameter is decreased, allowing much higher electric fields to be applied than in slab gel electrophoresis. A value of  $800 \text{ V cm}^{-1}$  is common, but much higher fields are starting to be used in high-speed CE. It is these higher electric fields that give rise to the high efficiency, increased separation power, and short analysis times characteristic of CE.

The second significant advantage of performing electrophoresis in capillaries is the elimination of convective flow. In electrophoresis chambers with large cross-sectional areas, thermal gradients created during electrophoresis induce convective mixing. This convection disrupts analyte bands, degrading separation efficiency. Gels were originally introduced into slab gel electrophoresis systems to prevent convection, not to improve the separation as is commonly thought. The capillary dimensions typically used in CE are too small for these convection currents to develop, allowing separations to be performed in free solution. The elimination of convective currents as a source of band broadening further contributes to the high efficiencies typically observed in CE.

## Capillary Chemistry

Fused silica capillaries are used almost exclusively in CE. Fused silica offers good mechanical stability and transparency and is relatively cheap and easy to obtain. The inner surface chemistry of these capillaries is determined by silanol functionalities. These silanols are weak acids that dissociate over a pH range

of 3–9. Therefore, under most separation conditions the capillary wall bears a negative charge, giving rise to EOF in the direction of the cathode. Often this is an advantage, allowing both cations and anions to be analyzed simultaneously. Many analytes, especially small neutral or negative molecules, show little interaction with the capillary wall, allowing the high efficiencies typically observed in CE.

There are many analytes that do interact with the negative silanols of the capillary wall though. Interactions with the wall introduce a mass transfer term into the peak broadening equation, often giving rise to peak tailing. Large molecules with cationic functional groups are most problematic. There are several approaches to modify the capillary surface chemistry for minimizing wall interactions. In some cases lowering the pH value below 3 will decrease interactions with cations. Most silanols are neutral at this pH, decreasing ionic interactions. There are many cases though where this solution is not practicable. Other options include permanent derivatization or dynamic coating of the capillary surface.

## Covalent Derivatization

Early wall coatings took advantage of silane coupling reactions that had been well characterized during the development of chromatographic stationary phases. Halo or alkoxyl silanes can be coupled to the capillary surface through the formation of siloxane bonds (see **Figure 2**). After this initial coupling, glycidoxyl functional groups are converted to the glyceryl derivative or substituted with another hydrophilic functionality such as polyacrylamide. These coatings were successful in diminishing EOF and minimizing protein–wall interactions. Unfortunately, siloxane bonds are easily hydrolyzed in moderately alkaline solutions, limiting their use to pH values below 8. More recently Grignard chemistry has been used to attach a vinyl functionality to the capillary surface through the formation of Si–C bonds. Free radical polymerization is initiated at the vinyl sites to complete the coating procedure. Linear polyacrylamides are most common, but polymers such as epoxides, diols, polyethylene glycol, polyvinyl alcohol (PVA), cellulose derivatives, dextran, and polyvinylpyrrolodone (PVP) have seen increasing use. The Si–C bond is much more stable to hydrolysis than the siloxane bond, allowing capillaries coated using this chemistry to be used over a wider pH range (2–10.5). Cationic (e.g., polyvinylamine) or anionic (e.g., 2-acrylamido-2-methylpropanesulfonic acid (NaAMPS)) polymers can be used in the final polymerization step as well. These charged coatings offer more reproducible EOF than uncoated

**Figure 2** Derivatization strategies for permanently coating the capillary surface. Si–O bonds are formed through silanization (A). Si–C bonds are formed using a Grignard reaction (B).

capillaries. In addition, cationic coatings can be used to reverse the direction of the EOF, which may be useful in optimizing certain separations.

## Dynamic Coatings

Noncovalent interactions can also be used to coat the capillary surface. Dynamic coatings can be generated by adding compounds to the separation buffer that interact with the capillary surface. Cationic surfactants such as cetyltrimethylammonium bromide (CTAB) form double layers over the capillary silanols when added to the buffer at concentrations higher than the critical micelle concentration, effectively coating the wall with a cationic surface. Similarly, neutral surfactants, such as Brij 35, can be used to coat the wall with a neutral surface. A potential drawback to this approach is that the introduction of micelles to the separation buffer can have dramatic effects on the separation. Other small polyamines (e.g., spermine and hexamethonium bromide) have been successfully used as dynamic coatings. Polyamines demonstrate a higher affinity for the capillary surface than do surfactants, allowing them to be effective at lower concentrations. In some cases it is possible to remove the additive from the separation buffer if the surface is regenerated by rinsing the capillary with the polyamine after several separations.

Hydrophilic polymers can be adsorbed onto the capillary surface to generate a neutral semipermanent coating. Examples include polysaccharides,

PVA, PVP, polyethylene oxide, and polyalkylene glycols. The properties of these polymers must be carefully balanced. More hydrophilic polymers tend to be most successful in decreasing interactions with proteins. Conversely, the stability of the coating increases with hydrophobicity.

## Capillary Gels

The development of capillary gels, analogous to slab gels, has largely been driven by the genomics boom. Separation of DNA fragments of varying length is not feasible in free solution CE. Initially capillaries were cast with permanent gels. Cross-linkers and extenders were added during the polymerization step described of the permanent polyacrylamide coatings described above. Gels of varying density can be generated by varying the concentration of the cross-linker. Although these gels made high-speed DNA sequencing possible, they suffered from short lifetimes and were relatively difficult to make. More recently polymeric solutions have been used as replaceable gels. High-pressure rinses are used to load capillaries with the polymer solutions. The polymer forms a cross-linked network if the concentration is above the entanglement concentration. This approach allows the gel to be replaced after every separation if necessary. Polymer concentration and size can be easily changed, giving increased options when optimizing the separation. Polyalkylene oxides

and polyalkylene glycols are commonly used as replaceable gels.

## Injection

As a general rule, less than 2–5% of the length of the capillary should be loaded with a sample to prevent the injection volume from significantly contributing to the peak width. For a 50 cm long, 50  $\mu\text{m}$  ID capillary, this corresponds to 20–50 nL, obviously much too small to be loaded using technologies developed for chromatography.

Electrokinetic injections are performed by placing the inlet of the capillary in the sample and applying a voltage for a set period of time. The quantity of analyte ( $Q$ ) loaded onto the capillary is described by

$$Q = \mu\pi r^2 E C t \quad [3]$$

where  $\mu$  is the analyte mobility,  $r$  is the capillary radius,  $E$  is the electric field,  $C$  is the analyte concentration, and  $t$  is the injection time. As shown in eqn [3], the amount of analyte injected depends in part on the mobility of the analyte. Analytes with higher mobility are preferentially injected over analytes with lower mobilities. This phenomenon is referred to as electrophoretic or electrokinetic bias. An electrokinetic bias can give rise to differing limits of detection (LODs) and peak widths for analytes, depending on their mobility. A less obvious drawback of electrokinetic injections is their high susceptibility to matrix effects. The electric field in the sample, and therefore the mobility of the analyte in the sample, is dependent on the sample conductivity. The amount of analyte injected is therefore highly dependent on the ionic strength of the sample.

Hydrodynamic injections are performed by inserting the inlet of the separation capillary into the sample and applying pressure at the inlet or vacuum at the outlet. The volume of sample injected ( $V$ ) is determined by

$$V = \frac{\Delta P D^4 \pi}{128 \eta L} \quad [4]$$

where  $\Delta P$  is the pressure difference between the inlet and outlet,  $D$  is the ID of the capillary,  $\eta$  is the viscosity of the separation buffer, and  $L$  is the length of the capillary. Siphoning can be used to perform a gravimetric injection. In this case  $\Delta P$  in eqn [4] is determined by

$$\Delta P = \rho g \Delta h \quad [5]$$

where  $\rho$  is the density of the sample,  $g$  is the gravitational constant, and  $\Delta h$  is the height difference

between the top of the inlet solution and the outlet solution. Hydrodynamic injections do not give rise to an injection bias. Additionally, matrix effects often have less of an effect on hydrodynamic injections. For these reasons hydrodynamic injections have become more common than electrokinetic injections, the exception being capillary gel electrophoresis, where the application of pressure disrupts the capillary gel. Both pressure and electrokinetic injections are usually available on commercial instruments. Research instruments built in-house are typically limited to electrokinetic or gravimetric injection.

## Capillary Cooling

As discussed above, Joule heating can become a significant contributor to band broadening at high electric fields, especially if high ionic strength buffers or large-diameter capillaries are used. Temperature fluctuations can also give rise to variability in migration times since the mobility is inversely proportional to the viscosity. A 10°C rise in separation buffer temperature can decrease the migration time by as much as 20%. Temperature control systems have become common components of commercially built instruments to help address these issues. Most systems pass air or liquid coolants over the separation capillary to dissipate Joule heat. Air cooling systems typically employ high flow rates (10  $\text{m s}^{-1}$ ) to improve heat dissipation. Liquid cooling systems have lower flow rates, but this is balanced by the higher heat capacity of the liquid coolant. Both systems work well to improve run-to-run migration time reproducibility. Typically capillaries can be thermostatted anywhere from 10°C below ambient temperature to  $\sim 60^\circ\text{C}$ .

## Power Supply

A high-voltage power supply is necessary for applying the electric field across the capillary. Power supplies with maximum outputs of  $\pm 30$  kV and 300  $\mu\text{A}$  are typical. Constant voltage, current, and power modes are often available, although most CE separations are performed in the constant voltage mode. Current monitoring is very useful in troubleshooting. When operating in the constant voltage mode the current should remain relatively constant throughout the separation. Spikes in current suggest partial blockage or breakage of the capillary. Similarly, no current across the capillary suggests complete blockage or breakage. Dual polarity power supplies are useful for cases where the analyte migration direction is reversed (e.g., a DNA separation in a neutral coated

capillary). By convention, normal polarity refers to the case where the anode is at the inlet of the capillary and the cathode is at the outlet. Reverse polarity refers to the case where the inlet potential is negative with respect to the outlet potential. The output potential should be relatively precise since variations in electric field contribute to irreproducibility in migration time. Precise timing is also necessary if electrokinetic injections are used. Platinum electrodes are used to make electrical contact with the inlet and outlet buffers. Platinum is chosen because of its inertness and long-term stability.

Performing separations at the 30 kV limit is not uncommon since separations often improve as the electric field is increased, assuming Joule heating does not become significant. Special precautions are necessary when applying higher voltages since the fields generated above 30 kV begin to approach the electric breakdown potential of air. The maximum current limit of the power supply is usually not a concern since Joule heating often becomes unacceptable at currents well below 300  $\mu\text{A}$ .

## Detectors

The progress of CE has been closely linked to the development of detector technology. Although the mass limits of detection (MLODs) for CE are often better than those for high-performance liquid chromatography (HPLC), the concentration limits of detection (CLODs) are usually orders of magnitude higher. The excellent MLOD is a result of the high peak efficiency typically observed in CE. Very little dilution of the analyte occurs during the separation in comparison with HPLC. Conversely, the dimensions of the capillary severely limit the CLOD. In an on-column detector, the detection volume significantly contributes to the peak width if the length of the detection region is greater than 100–200  $\mu\text{m}$ . In a 50  $\mu\text{m}$  ID capillary, this corresponds to a detection volume of only 100–200 pL, 10 000 times smaller than that of a typical HPLC detector. Even if the mass detection is excellent, the fact that it is in such a small volume limits the CLOD, forcing researchers in the CE field to push continually for further improvements in detector sensitivity.

## Absorbance Detectors

Ultraviolet (UV) and visible (Vis) absorbance are commonly used for detection in CE. The wavelengths available are limited by the UV-cutoff of the solvent and the fused silica capillary, allowing wavelengths as low as 190 nm to be used in aqueous solvents.

Many analytes contain aromatic or extended pi systems that absorb in this range, making UV–Vis somewhat universal detectors. Detection is performed on column. A narrow region of polyimide coating is removed from the separation capillary to make a detection window. Deuterium or tungsten lamps are common excitation sources in the UV and Vis wavelengths, respectively. Transmitted light is measured using photodiodes or photomultiplier tubes. Photodiode arrays can be used for multiple wavelength or full spectrum detection.

The on-column approach to CE absorbance detectors limits the path length to the ID of the CE capillary. The path length for a 50  $\mu\text{m}$  ID capillary will be 200 times shorter than that of a common 1 cm cuvette. The short path length significantly limits the sensitivity of CE absorbance detectors (see Table 2). A number of absorbance cells have been designed to increase the detection path length (see Figure 3). The

**Table 2** Representative LODs for CE detectors

Detector	Concentration LOD ( $\text{mol l}^{-1}$ )	Mass LOD (mol)
UV–Vis absorbance	$10^{-6}$ – $10^{-4}$	$10^{-15}$ – $10^{-13}$
Fluorescence	$10^{-16}$ – $10^{-6}$	$10^{-21}$ – $10^{-11}$
Amperometry	$10^{-8}$ – $10^{-6}$	$10^{-19}$ – $10^{-17}$
Conductivity	$10^{-8}$ – $10^{-7}$	$10^{-17}$ – $10^{-16}$
Potentiometry	$10^{-8}$ – $10^{-7}$	$10^{-17}$ – $10^{-16}$
MS	$10^{-9}$ – $10^{-5}$	$10^{-17}$ – $10^{-15}$

**Figure 3** High-sensitivity detection cells for UV–Vis absorbance CE detectors: (A) Z-cell; (B) bubble cell; and (C) multiple-reflection cell.

Z-cell introduces a flow through chamber parallel to the excitation beam, extending the path length to  $\sim 1$  mm. The ID of the bubble cell is widened at the detection point. The surface of the capillary can be coated with a reflective coating to make a detection cell where the excitation beam crosses the capillary multiple times. All these approaches offer a modest improvement in sensitivity at the expense of an increased detection volume, which can increase the observed width of the analyte peaks.

The optical properties of an on-column detection cell are far from ideal. During CE's early development, HPLC absorbance detectors were used. Unfortunately the dimensions of the capillary are much smaller than the typical HPLC absorbance cell. Much of the excitation light did not pass through the capillary and scatter was high. The circular cross-section of the capillary gives rise to varying path lengths across the excitation beam. The combination of high scatter and variation in excitation beam path length limited the linear range of early CE detectors. More recent absorbance detectors incorporate a ball lens to focus light through the center of the capillary, decreasing both scatter and variation in path length. This optical arrangement decreases detector noise 100-fold and increases the linear range to over three orders of magnitude.

## Fluorescence

Of the CE detectors available, fluorescence is by far the most sensitive. Mass detection limits have been reported as low as a single molecule. CLOD values routinely approach  $<10^{-13} \text{ mol l}^{-1}$ . Unfortunately, most analytes are not natively fluorescent, making sample derivatization necessary. Labeling protocols for many functional groups, including amines, carboxylic acids, and thiols, have been developed.

Lasers are almost exclusively used as the excitation source in CE detectors. The low output divergence of lasers allows the excitation beam to be easily focused to a spot on the size scale of the ID of the capillary, giving rise to high excitation intensity and less scatter. Laser technology is constantly improving, making gains in reliability and affordability. Lasers are available with emission lines across the visible region of the spectrum. Development of lasers that emit deep into the UV has made native fluorescence detection of proteins and DNA increasingly feasible.

Fluorescence detection is usually performed on column, using an approach similar to that described for absorbance detectors. Excitation is collected through an objective at  $90^\circ$  to the excitation beam. Filters and field stops are used to block scatter and

pass fluorescence. Care must be used when choosing excitation and emission wavelengths to minimize the background signal generated by Raman scattering from the solvent. Fluorescence is usually detected using high-sensitivity photomultiplier tubes, although recent advances have made charge coupled device detection more common.

As discussed with absorbance detectors, the circular shape of the capillary makes for a nonideal optical arrangement when performing on-column fluorescence detection. The excitation beam is scattered over  $\sim 360^\circ$  at the air-fused silica and to a lesser extent the fused silica–buffer boundaries. Impurities in the fused silica capillary also contribute to the background fluorescence. Development of high-sensitivity fluorescence detection cells for CE has been an area of active research. The most successful design has been the sheath-flow cuvette (see **Figure 4**). The outlet of the capillary is positioned in a quartz cuvette ( $2 \text{ mm} \times 2 \text{ mm}$  square with a  $200 \mu\text{m} \times 200 \mu\text{m}$  square bore, optical quality). The separation buffer is flowed around the outlet of the separation capillary, pulling the analyte off the capillary in a laminar flow profile. LIF is performed off column in this laminar flow region, spatially isolating the fluorescence signal from the background fluorescence and the scatter that occur at the cuvette walls. The sheath-flow cuvette typically improves the S/N ratio by  $>100$ -fold when compared with on-column fluorescence detectors.

**Figure 4** Schematic of a sheath-flow, high-sensitivity, off-column LIF detection cell.

## EC Detection

EC detection has become increasingly popular over the past several years. EC detectors offer excellent sensitivity and in some cases selectivity. A wide range of analytes can be detected using EC. There are four modes of EC detection that have found use in CE: amperometry, conductivity, voltammetry, and potentiometry.

Amperometric detection has seen the most use to date. In this approach an electrode is placed near or in the outlet of the separation capillary. The electrode is held at a fixed potential. The current is measured as the analyte undergoes redox chemistry at the electrode. Amperometric detection is usually performed in the oxidative mode since dissolved oxygen in the separation buffer interferes with detection in the reductive mode. Electrodes are usually made of carbon fibers or glassy carbon. Several electrode designs have been implemented (see Figure 5). The most common approach is to place a disk electrode at the outlet of the capillary. Conversely, a carbon fiber can be inserted into the end of the capillary. Inserting a carbon fiber electrode into the end of the capillary decreases the detection volume, improving the peak shape. The oxidation efficiency, and therefore the sensitivity, is also improved since the analyte must migrate past the electrode surface to exit the capillary. The oxidation efficiency, and therefore the signal, is dependent on reproducibly positioning the electrode, which may have limited the spread of EC CE detectors. Another concern is isolating the detection electrode from the electric field generated by the separation voltage. Off-column disk electrodes are

**Figure 5** Disk and carbon fiber electrodes used in amperometric and voltammetric CE detectors.

only minimally affected by the separation potential if the separation current is kept low and the electrode is placed a reasonable distance from the capillary outlet. When on-column carbon fibers are used, the separation voltage must be grounded before the amperometry electrode. The capillary can be fractured or etched to provide a route for closing the circuit. The gap created to complete the CE circuit must be small enough to prevent a significant amount of analyte from escaping from the capillary. Palladium decouplers and electrically isolated potentiostats have also been employed for isolating the amperometry electrode.

Conductivity detection is performed by measuring the current between two electrodes. Most analytes analyzed using CE will be ionic and therefore should give rise to a change in conductivity. An AC voltage is used in the conductivity cell to prevent faradic reactions. Unfortunately, the LODs for conductivity detectors are higher than those for amperometry because small changes in buffer composition give rise to noise at the detector.

Voltammetric detection is performed by measuring the redox current at an electrode at the end of the capillary. The current is related to the analyte concentration, and the correlation of the onset potential and the peak current gives information about the identity of the analyte. The same electrode arrangements used in amperometric detection can be used in voltammetric detectors. The LODs using voltammetry are much poorer than with amperometric detectors due to capacitive charging and nonfaradic current generated when the potential is cycled.

Ion-selective electrodes are used in potentiometric detectors. Early designs inserted micropipette electrodes into the outlet of the separation capillary. The capillary outlet was widened using etching to make placement easier and decrease the electric field at the electrode. As such it was found that electrical decoupling was unnecessary. More recent designs have used coated wire electrodes where a solid wire is coated with a polyvinyl chloride membrane. The electrode is placed  $\sim 50\ \mu\text{m}$  from the outlet of the capillary. Coated wire electrodes are much less fragile and easier to position than micropipette electrodes.

## Mass Spectrometry

Mass spectrometry (MS) detection in CE has grown enormously over the past decade. MS detection is very sensitive and is well suited to the small sample volumes typical of CE. MS also provides structural information about the analytes, often allowing

unambiguous peak identification, a feature not available with other detection schemes. Most analytes can be analyzed using MS, making this a nearly universal detection approach.

The major difficulty in the initial development of MS detectors was the coupling of CE, a liquid-based technique, with MS, a gas phase analysis. Electrospray ionization (ESI) interfaces have found the most use to date. In contrast with HPLC, where flow rates need to be attenuated, the flow rates in CE are generally too small ( $\sim 1\text{--}100\text{ nL min}^{-1}$ ) to support an electrospray in a standard interface. A sheath flow was introduced to add additional volume to the CE buffer. The voltage applied to the sheath flow both generates the electrospray and closes the CE circuit (see Figure 6).

More recently sheathless-flow ESI interfaces, also referred to as nanospray interfaces, have been developed for CE. The electrospray is generated directly at the tip of the capillary. The capillary outlet is pulled to a tapered tip to reduce the flow rate and maximize the electric field, thereby stabilizing the electrospray at flow rates as low as several nanoliters per minute. The S/N ratio is greatly improved over sheath-flow ESI interfaces since there is no dilution of the analytes as they exit the capillary. Several approaches have been developed for applying the electrospray voltage (and completing the CE circuit) at the capillary outlet. Early designs coated the tip of the capillary outlet with gold, allowing an electrical connection to be made. Although successful, these

gold-coated tips had relatively short lifetimes due to EC and electrical degradation. Nanospray tips have been coupled to the outlet of the CE capillary in low-dead volume stainless steel unions or Nafion tubing. In this arrangement the electrical connection is made through the gap between the CE outlet and the nanospray tip. A downside of this approach is the relatively large dead volume of the interface, which can lead to peak broadening. A wire can be inserted into the CE capillary outlet or a hole near the outlet to complete the ESI and CE circuits. Again, while this approach is successful, it is not without drawbacks. The CE capillary must have an ID  $> 25\text{ }\mu\text{m}$  to admit the wire. This is unfortunate since the S/N ratio increases dramatically as the diameter of the nanospray tip is decreased.

Sheath-flow and nanospray ESI interfaces have successfully coupled CE to almost every mode of MS including the use of quadrupole, time-of-flight, ion-trap, and magnetic sector instruments. CE-MS has been employed in the analysis of a wide range of analytes but has been especially successful in biological assays. The mass selectivity of MS detection is especially useful in complex DNA, protein, and carbohydrate separations.

## Safety

Researchers should be reminded that CE makes use of relatively high voltages (up to 30 kV). Although the current is limited to 300  $\mu\text{A}$  in many CE power supplies, the potential for injury should be respected. CE instruments are often housed in Plexiglas boxes to prevent accidental exposure to high voltages. An interlock is used to disengage the high voltage automatically if the box is opened without first turning off the CE power supply. Similar safety features are present on commercially built CE instruments.

### Introduction

Although chromatographic techniques such as gas chromatography (GC) and (primarily) high-performance liquid chromatography (HPLC) are still used in most industrial laboratories for the analysis of drugs and excipients, capillary electrophoresis (CE) has been increasingly applied to analyze pharmaceuticals in recent years. CE can be operated at a similar performance and level of automation as HPLC and has in many instances advantages compared to HPLC in terms of rapid method development and lower operating costs due to reduced consumption of chemicals and samples. However, the major strength of CE is the fact that the separation principle is different from chromatographic techniques so that CE and HPLC in fact form a powerful combination for the analysis of complex molecules. Generally, the scope of applications of CE in pharmaceutical analysis is identical to that of HPLC. Therefore, often a choice between the two techniques has to be made.

In recent years, an increasing number of pharmaceutical companies have included CE methods in early drug discovery testing and routine quality control as well as in documents for regulatory submission. CE methods are accepted by the regulatory authorities such as the US Food and Drug Administration and the European Agency for the Evaluation of Medicinal Products and the technique has been implemented as analytical method by the United States Pharmacopeia and the European Pharmacopoeia.

Based on the number of publications, drugs are actually the preferred analytes in CE. While they served as model compounds for the investigation of specific aspects in some studies, CE has been used to solve ‘real’ pharmaceutical problems in the majority

of applications. Besides small molecules, inorganic ions, peptides, and proteins, oligonucleotide pharmaceuticals have also been analyzed. In addition to pharmaceutical applications, CE is also utilized as an analytical technique by the chemical, cosmetic, and food industries as well as in environmental and forensic analysis.

### Modes of Operation

With respect to small molecules, capillary zone electrophoresis (CZE) for charged molecules and micellar electrokinetic chromatography (MEKC) for the analysis of uncharged compounds has been applied. However, the MEKC mode may also be applied to charged analytes in order to enhance the separation selectivity of a given separation. Enantiomer separations generally require the presence of a chiral selector. For the analysis of large biomolecules such as nucleic acids and proteins, capillary gel electrophoresis (CGE) and capillary isoelectric focusing (CIEF) have also been applied. Isotachophoretic techniques are primarily used for sample concentration.

### Method Development, Validation, and System Suitability

The aim of method development in any analytical separation technique is to obtain an assay that allows the successful separation of the analytes of interest in a short analysis time, with high reproducibility and ruggedness. In CE, factors such as buffer pH, molarity and type of the background electrolyte, applied voltage, temperature of the capillary, and buffer additives such as surfactants, organic solvents, ion-pairing reagents, complexing agents influence a separation. In recent years, chemometrics have been employed to minimize the number of experiments upon definition of the dominant variables of a given separation.

### Introduction

Although chromatographic techniques such as gas chromatography (GC) and (primarily) high-performance liquid chromatography (HPLC) are still used in most industrial laboratories for the analysis of drugs and excipients, capillary electrophoresis (CE) has been increasingly applied to analyze pharmaceuticals in recent years. CE can be operated at a similar performance and level of automation as HPLC and has in many instances advantages compared to HPLC in terms of rapid method development and lower operating costs due to reduced consumption of chemicals and samples. However, the major strength of CE is the fact that the separation principle is different from chromatographic techniques so that CE and HPLC in fact form a powerful combination for the analysis of complex molecules. Generally, the scope of applications of CE in pharmaceutical analysis is identical to that of HPLC. Therefore, often a choice between the two techniques has to be made.

In recent years, an increasing number of pharmaceutical companies have included CE methods in early drug discovery testing and routine quality control as well as in documents for regulatory submission. CE methods are accepted by the regulatory authorities such as the US Food and Drug Administration and the European Agency for the Evaluation of Medicinal Products and the technique has been implemented as analytical method by the United States Pharmacopeia and the European Pharmacopoeia.

Based on the number of publications, drugs are actually the preferred analytes in CE. While they served as model compounds for the investigation of specific aspects in some studies, CE has been used to solve ‘real’ pharmaceutical problems in the majority

of applications. Besides small molecules, inorganic ions, peptides, and proteins, oligonucleotide pharmaceuticals have also been analyzed. In addition to pharmaceutical applications, CE is also utilized as an analytical technique by the chemical, cosmetic, and food industries as well as in environmental and forensic analysis.

### Modes of Operation

With respect to small molecules, capillary zone electrophoresis (CZE) for charged molecules and micellar electrokinetic chromatography (MEKC) for the analysis of uncharged compounds has been applied. However, the MEKC mode may also be applied to charged analytes in order to enhance the separation selectivity of a given separation. Enantiomer separations generally require the presence of a chiral selector. For the analysis of large biomolecules such as nucleic acids and proteins, capillary gel electrophoresis (CGE) and capillary isoelectric focusing (CIEF) have also been applied. Isotachophoretic techniques are primarily used for sample concentration.

### Method Development, Validation, and System Suitability

The aim of method development in any analytical separation technique is to obtain an assay that allows the successful separation of the analytes of interest in a short analysis time, with high reproducibility and ruggedness. In CE, factors such as buffer pH, molarity and type of the background electrolyte, applied voltage, temperature of the capillary, and buffer additives such as surfactants, organic solvents, ion-pairing reagents, complexing agents influence a separation. In recent years, chemometrics have been employed to minimize the number of experiments upon definition of the dominant variables of a given separation.

Generally, water-soluble charged compounds are analyzed by CZE. Typical method development starts with the selection of an appropriate buffer pH followed by investigation of the other variables. Standard conditions using a pH 2.5 phosphate buffer have been developed for the analysis of basic drugs. A general method for the separation of acidic drugs uses a pH 9.5 borate buffer. However, it may also be suitable to investigate the pH range close to the  $pK_a$  values of compounds especially in the case of structurally closely related compounds and diastereomers. Suppression of the electroosmotic flow (EOF) can be obtained by dynamic or permanent coating of the capillary wall. Many reagents and methods for this purpose have been described. When selectivity requirements exceed mobility differences obtainable by CZE then MEKC conditions can be applied. Sodium dodecyl sulfate (SDS) is often employed but many other surfactants are available. Type and concentration of the surfactant are important factors that need to be considered. Alternatively, the use of complexing agents and chiral selectors may increase the selectivity of a given separation system. MEKC is also suitable for the simultaneous analysis of charged and neutral compounds. Furthermore, MEKC is the method of choice for neutral or water-insoluble compounds, for example, steroids or lipid-soluble vitamins. The addition of organic solvents such as methanol, ethanol, 2-propanol, acetonitrile to the background electrolyte further increases the solubility of the analytes in the background electrolyte. Alternatively, nonaqueous conditions can be employed for the analysis of water-insoluble drugs. The separation of enantiomers can be achieved by the indirect method upon derivatization with stereochemically pure reagents or by direct separation of the enantiomers, which generally requires the addition of a chiral selector to the background electrolyte in CZE as well

as MEKC. Numerous types of chiral selectors are commercially available (see below). Type and concentration of a chiral selector need to be evaluated during method development. Combinations of chiral selectors may apply.

As in other analytical techniques, careful and comprehensive method validation is also required in CE in order to obtain a reproducible and rugged method that is suitable for routine analysis and may be accepted by the regulatory authorities. Generally, the same principles apply for CE as for chromatographic techniques depending on the scope of the analysis but some specifics apply (Table 1).

Selectivity (sometimes also termed specificity) is the ability of a method to discriminate an analyte from potentially interfering substances including the matrix. As the selectivity will be particularly altered by a buffer pH that is close to the  $pK_a$  of the analytes and electrolysis of the background electrolyte will inevitably occur, buffer capacity, volume of the electrolyte reservoir, applied current, and the period of time of buffer usage have to be considered. In addition, when using derivatized chiral selectors such as cyclodextrins for enantiomer separations, it should be confirmed that different batches of the selectors from different suppliers give similar performance because the degree of substitution, polydispersity, or purity of the selectors may alter the selectivity. Commercially available randomly substituted cyclodextrins are a mixture of positional isomers with different numbers of substituents. Peak areas in CE depend on the velocity by which analytes travel through the detector cell. Thus, for obtaining accurate results corrected peak areas, i.e., peak area divided by the respective migration time, have to be used for correcting the different residence times of the compounds in the detector cell. In addition, ionization of the analytes or complexation by buffer

**Table 1** Validation requirements in capillary electrophoresis

Characteristic	Identification	Achiral or chiral impurities		Main component assay

additives may alter the response factors in ultraviolet (UV) detection compared to HPLC.

The linearity as a function of the detection signal and the analyte concentration should be evaluated depending on the type of the assay. Thus, a method for the determination of the main component may be calibrated in the range of 50–150% or 80–120% while the linearity of an impurity should be determined in the presence of the main constituent around the maximally tolerated level of the impurity, for example, from the limit of quantitation to 200% of the tolerated level. In bioanalysis, a wider range has to be explored covering two to three orders of magnitude in concentration. The linear range of UV detectors in CE is more restricted than in HPLC due to the circular geometry of the capillary. Moreover, for indirect UV detection the linear range is more restricted compared to direct UV detection.

Precision as the variability of the individual measurements is generally lower compared to HPLC due to the small injection volumes that may vary with altered viscosity or temperature of the test solutions. The use of an internal standard is recommended to correct for injection errors. In addition, the influence of the capillary has to be evaluated by testing capillaries from different batches and suppliers and by carefully validating capillary pretreatment, rinsing, and storage procedures. In routine analysis, capillaries should be dedicated to only one specific application with defined experimental conditions. This is especially true for MEKC methods. The purity of the electrolytes and chiral selectors also has to be considered. As in HPLC the stability of test and reference solutions should be assessed, but in contrast to HPLC, where large volumes of the mobile phase are consumed, only a small volume of electrolyte solution is used in CE. Typically, 500–1000 ml of the background electrolyte is prepared at a time but the shelf life of the solutions may vary depending on the composition.

Robustness as a measure of the method to remain unaffected by small but deliberate variations of the experimental conditions is not listed in the ICH guidelines of method validation but is an important characteristic that should be part of any validation procedure. The most relevant factors such as buffer pH and composition, concentration of a chiral selector, temperature, rinse conditions and times are varied around the values of a method and evaluated. In addition, experimental design has been used for robustness testing allowing assessing the interaction of different factors. Response surface plots give an impression of the variations that can be expected. Robustness testing is especially easy in CE due to the

short equilibration time when changing the composition of the electrolyte.

Method transfer between instruments and laboratories may require some revalidation in CE due to differences in the construction of the instruments, especially the detector and injection systems. Therefore, it is preferable to specify an injection volume that is independent of a specific instrument. To assess the performance of a method in routine analysis system suitability tests comparable to HPLC such as selectivity, resolution, or system precision are recommended. Peak symmetry is not considered as the injection of high concentration often leads to peak distortion in CE.

## Main Component Analysis

A large number of reports have documented that precision and accuracy of CE methods for quality control of pharmaceuticals are comparable to HPLC analyses. RSDs  $\leq 1\%$  can be achieved by carefully controlling the operational parameters. A single set of experimental conditions often allows the analysis of a range of structurally diverse compounds. The use of an internal standard is generally recommended to correct for injection errors. The standard should be selected in such a way that it is well separated from the main component and related substances. Sample preparation steps consist of simple filtration in the case of the analysis of solid dosage forms; solutions can be injected directly upon suitable dilution if necessary. Thus, CE methods have been employed for the analysis of drug substances and pharmaceutical formulations (Table 2) and have been included in regulatory submission files.

Synthetic as well as herbal drugs have been determined by CE. In addition, starting materials of drug synthesis and excipients such as carbohydrates, sweeteners, preservatives, surfactants, dyes, lecithin, fatty acids, solubilizers can be analyzed. CE methods can also be effectively applied to determine the composition of drugs derived from natural or genetically modified organisms that are a mixture of closely related compounds such as the antibiotics erythromycin or gentamicin (Figure 1). In addition to small molecules, CE is increasingly used for the characterization of recombinant protein pharmaceuticals. Examples include insulin, human growth hormone, human platelet-derived growth factor, human epidermal growth factor, interferons, therapeutic monoclonal antibodies, a soluble tumor necrosis factor- $\alpha$  receptor, somatotropin, cytokines, and immunoglobulins. The CE methods employed include CZE, CIEF, and CGE. CE-SDS, which is analogous to SDS-polyacrylamide

**Table 2** Examples of validated capillary electrophoresis methods for main component analysis of pharmaceuticals

<i>Drug</i>	<i>Sample</i>	<i>Mode</i>	<i>Conditions</i>
Amoxicillin and clavulanic acid	Injection	MEKC	Sodium borate-phosphate, pH 8.66, 1.44% SDS
Ampicillin and sulbactam	Injection	MEKC	Sodium borate-phosphate, pH 8.66, 1.44% SDS
Benzalkonium chloride	Ophthalmic solutions	CZE	Sodium phosphate, pH 4.0, 40% acetonitrile
Cephalexin	Oral suspension	MEKC	Sodium tetraborate, 20 mmol l <sup>-1</sup> SDS, 0.1% laurylpolyoxyethylenic ether
Clodronate	Liposomal formulation	CZE	1-Nitroso-2-naphthol-3,6-disulfonic acid disodium salt, pH 8.0
Diclofenac sodium	Tablet	CZE	Sodium tetraborate, pH 9.23
Enoxacin	Tablets	CZE	Sodium tetraborate, pH 8.6
Fluoxetine	Capsules	CZE	Sodium phosphate, pH 2.5
Formoterol	Inhaler capsules	CZE	Sodium phosphate, pH 2.5, 20% acetonitrile
Lansoprazole	Capsules	CZE	Sodium tetraborate, pH 8.7
Meloxicam	Tablets	CZE	Sodium tetraborate, pH 8.5, 5% methanol
Mirtazapine	Tablets	CZE	Sodium phosphate, pH 7.0
Nimesulide	Tablets	CZE	Sodium tetraborate, pH 8.1, 10% ethanol
Reboxetine	Tablets	CZE	Sodium phosphate, pH 2.5
Rufloxacin hydrochloride	Drug substance, tablets	CZE	Sodium borate, pH 8.8
Salbutamol	Tablets, syrup	CZE	Sodium acetate, pH 5.0, 13 mg ml <sup>-1</sup> CM- $\beta$ -CD
Tobramycin	Drug substance	CZE	Sodium tetraborate, pH 10.2, 25% acetonitrile
Ursodeoxycholic acid	Tablets	CZE	Sodium <i>p</i> -hydroxybenzoic acid, pH 8.0
Ximelagatran	Drug substance, tablets	CZE	Sodium phosphate, pH 1.9, 10% acetonitrile, 11 mmol l <sup>-1</sup> HP- $\beta$ -CD
Recombinant human epidermal growth factor	Injection	MEKC	Sodium tetraborate, pH 8.5, 12.5 mmol l <sup>-1</sup> SDS

SDS, sodium dodecylsulfate; HP- $\beta$ -CD, hydroxypropyl- $\beta$ -cyclodextrin; CM- $\beta$ -CD, carboxymethyl- $\beta$ -cyclodextrin.

gel electrophoresis, can provide a size-based fingerprint of a product with respect to size variants from the desired product such as aggregates and fragments. Compared to classical gel electrophoresis CE provides greater automation. CE allows the detection of different isoforms and glycoforms of proteins. One example is the determination of the glycoforms of recombinant erythropoietin as one of the tests of the European Pharmacopoeia (Figure 2). In addition to quantitation data, CE can provide information on the degradation profile of peptides and proteins such as aggregation, cleavage, deamidation, or oxidation. A problem that may be encountered in protein analysis is the adsorption of proteins to the capillary wall that will greatly reduce the reproducibility and ruggedness of a method. However, several strategies have been developed to minimize wall adsorption such as operating at extreme pH values, the use of buffer additives (ionic compounds, polyamines, surfactants, etc.), and dynamic or permanent coating of the capillary surface.

## Determination of Drug-Related Impurities

In pharmaceutical analysis, the demonstration of the purity of a drug as a substance or in a formulation is

essential. Besides impurities that can be explained as reaction by-products or degradation products often unknown impurities may be present. As a high-resolution technique CE is suitable for analyzing related substances in drugs as demonstrated by a large number of sensitive, validated methods (Table 3). CZE as well as MEKC assays have been elaborated and CE methods were included in regulatory submission files. Predominantly small synthetic molecules have been analyzed but there are also examples for large compounds such as proteins. Often, identical operational parameters suitable for main component analysis can be applied to the determination of the impurities. In addition to the analysis of the purity of pharmaceuticals, CE may also be used for the profiling of illicit drugs in forensic sciences. For the determination of the chiral purity of drugs see section on chiral analysis.

Currently, regulatory agencies demand the identification and quantitation of impurities at the 0.1% level. The revised ICH guideline Q3A that came into operation in August 2002 states that impurities have to be reported if they are present above 0.05% (reporting threshold), identified if above 0.1% (identification threshold), and qualified if above 0.15% (qualification threshold). These limits apply to drugs with a maximum daily dose of 2 g per day and lower limits apply for a drug with a higher daily

**Figure 1** Electropherogram of a commercial sample of gentamicin sulfate following derivatization with  $\alpha$ -phthalaldehyde (OPA) and thioglycolic acid; IS internal standard (picric acid), a–h unknown impurities. Experimental conditions: 24.5/33 cm fused-silica capillary, 50  $\mu\text{m}$ , 100  $\text{mmol L}^{-1}$  sodium tetraborate buffer, pH 10.0, 20  $\text{mmol L}^{-1}$  sodium deoxycholate, 15  $\text{mmol L}^{-1}$   $\beta$ -cyclodextrin, 12 kV, UV detection at 340 nm. (Reproduced with permission from Wiene F and Holzgrabe U (2003) A new micellar electrokinetic capillary chromatography method for separation of the components of aminoglycoside antibiotics. *Electrophoresis* 24: 2948–2957; © Wiley-VCH.)

intake. **Figure 3** shows the analysis of a sample of levofolinic acid spiked with 0.1% of related substances including the diastereomer (6*R*,2'*S*)-folinic acid. CE assays with a limit of detection as low as 0.001% of the main component have been reported (**Table 3**). The identification or confirmation of unknown impurities can be performed by coupling of

CE to mass spectrometry (MS). In addition, CE and HPLC are complementary techniques due to the different respective separation mechanisms. Therefore, CE and HPLC represent a powerful combination especially for the purity determination of drugs. CE can be used to verify HPLC impurity data and vice versa.

## Determination of Inorganic Ions

Inorganic ions as counterions of acidic and basic drugs and as constituents in parenteral solutions can be analyzed by CE using indirect UV detection.

**Figure 2** Reference electropherogram of erythropoietin of the European Pharmacopoeia. (Reproduced with permission from the *European Pharmacopoeia*, 4th edn. (2002). Strasbourg, France: European Directorate for the Quality of Medicines.)

Typically, electrolytes containing imidazole or benzylamine derivatives have been employed for the determination of metal ions such as potassium, sodium, calcium, or magnesium. Complexing agents including hydroxyisobutyric acid, lactic acid, citric acid, or tartaric acid may be added as the differences in the electrophoretic mobility of metal cations in the co-electroosmotic mode are not always sufficient for a separation. The analysis may also be performed in nonaqueous electrolytes consisting of acetic acid and imidazole in methanol. Inorganic anions such as chloride, sulfate, or nitrate have been analyzed using chromate as UV-absorbing electrolyte co-ion. Tetradecyltrimethylammonium bromide or other quaternary ammonium compounds have been added in order to reverse the EOF. The organic anionic counterions acetate, succinate, maleate, citrate, or tartrate were determined by indirect UV detection using phthalate-containing buffers.

## Chiral Analysis

Chiral analysis is probably the premier application of CE due to the generally high resolution of the technique. Enantioseparations can be performed by the

**Table 3** Examples of validated capillary electrophoresis methods for the determination of related substances in pharmaceuticals

Drug	Sample	Conditions	LOD/LOQ of impurities
Alcuronium chloride	Drug substance, injection	Potassium phosphate, pH 5.5, 12 mmol l <sup>-1</sup> DM- $\beta$ -CD	LOD 0.1%, LOQ 0.2%
Calcium levofolinate	Drug substance	Sodium tetraborate, pH 9.9, 20 mg ml <sup>-1</sup> DM- $\beta$ -CD	LOD 0.025-0.05%, LOQ 0.05-0.1%
Cefalexin	Drug substance	Sodium acetate, pH 5.25, 50 mmol l <sup>-1</sup> SDS	LOD 0.05%, LOQ 0.1%
3,4-Diaminopyridine	Drug substance	Sodium phosphate, pH 2.5	LOD 0.025%, LOQ, 0.05%
Glutathione	Drug substance	Sodium phosphate, pH 1.8	LOD 0.002-0.008%, LOQ 0.005-0.02%
Kanamycin	Drug substance	Sodium tetraborate, pH 10.0, 16.0% methanol Derivatization with 1,2-phthalic dicarboxaldehyde/mercaptoacetic acid	LOQ 0.14%
Loratadine	Drug substance	Sodium phosphate, pH 2.5, 10% methanol	LOQ 0.05%
Metacycline	Drug substance	Sodium carbonate, pH 10.35, 1 mmol l <sup>-1</sup> EDTA, 13% methanol	LOD 0.024%, LOQ 0.06%
Mirtazapine	Drug substance	Sodium phosphate, pH 2.0, 25% methanol	LOD 0.02-0.04%, LOQ 0.06-0.13%
Protegrin IB-367	Drug substance	Sodium phosphate, pH 2.6	LOD 0.05%, LOQ 0.5%
Ranitidine hydrochloride	Drug substance, injection	Sodium citrate, pH 2.6	LOD 0.05%, LOQ 0.1%
Spiramycine	Drug substance	Sodium phosphate, pH 7.5, 12 mmol l <sup>-1</sup> CTAB, 20 mmol l <sup>-1</sup> sodium cholate	LOD 0.025%, LOQ 0.08%
Ximelagatran	Drug substance, tablets	Sodium phosphate, pH 1.9, 10% acetonitrile, 11 mmol l <sup>-1</sup> HP- $\beta$ -CD	LOQ 0.05%

CTAB, cetyltrimethylammonium bromide; EDTA, ethylenediaminetetraacetic acid; LOQ, limit of quantitation; LOD, limit of detection; DM- $\beta$ -CD, dimethyl- $\beta$ -cyclodextrin; HP- $\beta$ -CD, hydroxypropyl- $\beta$ -cyclodextrin.

**Figure 3** Separation of levofolinic acid and related substances at the 0.1% level; 1, levofolinic acid; 2, (6*R*,2'*S*)-folinic acid; 3, dihydrofolinic acid; 4, folic acid; 5, *N*-(4-aminobenzoyl)-L-glutamic acid; 6, 10-formylc acid; IS, internal standard (methotrexate). Experimental conditions: 40/50 cm fused-silica capillary, 50  $\mu\text{m}$ , 40 mmol  $\text{L}^{-1}$  sodium tetraborate buffer, pH 9.9, 20 mg  $\text{mL}^{-1}$  heptakis-(2,6-di-*O*-methyl)- $\beta$ -cyclodextrin, 21 kV, UV detection at 214 nm. (Reproduced with permission from Süß F, Harang V, Sängers-van de Griend CE, and Scriba GKE (2004) Development and validation of a robust capillary electrophoresis method for impurity profiling of calcium levofolinate including the (6*R*,2'*S*)-diastereomer using statistical experimental design. *Electrophoresis* 25: 766–777; © Wiley-VCH.)

indirect method upon derivatization with a stereochemically pure agent to form diastereomers that are subsequently separated in an achiral system. The direct enantioseparation, which is by far the most popular technique in chiral CE, is based on the formation of transient diastereomeric complexes between the analyte enantiomers and an optically pure chiral selector added to the background electrolyte.

While the migration principle, i.e., the driving forces moving the analytes through the separation capillary, is based on electrophoretic mechanisms the chiral separation is based on enantioselective interactions between the analyte enantiomers and a chiral selector and is, therefore, a chromatographic separation principle. The fact that the selector is in the same phase as the analytes in CE and not part of a stationary phase that is immiscible with the mobile phase as found in chromatography does not represent a conceptional difference between both techniques. The chiral selector in CE is also called pseudophase as it is not a physically different phase and may also possess an electrophoretic mobility. Enantioseparations in CE have also been termed 'capillary electrokinetic chromatography'.

The chiral selectors applied to CE include native cyclodextrins as well as neutral and charged derivatives, oligo- and polysaccharides, chiral crown ethers,

**Figure 4** Simultaneous chiral separation of the isomeric tripeptides Gly- $\alpha$ -Asp-PheNH<sub>2</sub> and Gly- $\beta$ -Asp-PheNH<sub>2</sub>. Experimental conditions: 40/47 cm polyacrylamide-coated capillary, 50  $\mu\text{m}$ , 50 mmol  $\text{L}^{-1}$  sodium phosphate buffer, pH 5.25, 60 mg  $\text{mL}^{-1}$  carboxymethyl- $\beta$ -cyclodextrin, –20 kV, UV detection at 215 nm. (Reprinted with permission from Sabah S and Scriba GKE (1998) Electrophoretic stereoisomer separation of aspartyl dipeptides and tripeptides in untreated fused-silica and polyacrylamide-coated capillaries using charged cyclodextrins. *Journal of Chromatography A* 822: 137–145; © Elsevier.)

macrocytic glycopeptide antibiotics, proteins and synthetic cyclopeptides, calixarenes, as well as chiral surfactants derived from steroids, amino acids, tartaric acid, or glycosides. In addition, ligand exchange and chiral ion-pairing reagents have been used for enantioseparations. Among these compounds, cyclodextrins are by far the most common chiral selectors applied to enantioseparations. Numerous neutral and charged cyclodextrin derivatives are commercially available. Charged cyclodextrins also allow the analysis of neutral compounds. The resolving power of chiral CE is demonstrated by the simultaneous separation of the enantiomers of the isomeric tripeptides Gly- $\alpha$ -Asp-PheNH<sub>2</sub> and Gly- $\beta$ -Asp-PheNH<sub>2</sub> (Figure 4).

For method optimization of chiral separations the type and concentration of the chiral selector has to be specifically considered in addition to factors also important in achiral CE such as pH, molarity and type of the background electrolyte, and buffer additives. When using randomly substituted cyclodextrins as chiral selectors testing of different batches of the cyclodextrin and samples from different suppliers is

recommended to ensure sufficient robustness of the method. In addition to aqueous background electrolytes, the use of nonaqueous solvents is becoming increasingly popular. Nonaqueous solvents may offer the advantage of increased solubility of chiral selectors and samples, lower Joule heating, or reduced solute-wall interactions. Moreover, an increase in selectivity can often be observed in nonaqueous media. The modes of chiral CE separations include partial filling and counter-current techniques, carrier-mode separations, mobility counterbalanced separations, etc.

Chiral CE has been applied to the determination of the chiral purity of drugs and racemate composition. Drug substances and pharmaceutical formulations have been analyzed and chiral CE methods have been included in regulatory submission files. As an example, the determination of the chiral purity of (*S*)-ropivacaine is shown in Figure 5. Further examples of chiral CE drug analysis using cyclodextrins as chiral selectors listed in Table 4 underline the performance capability of CE methods. ICH guideline Q3A on impurities in new drug substances explicitly

Drug	Selector	Background electrolyte	LOD/comment
DOPA, carbidopa	S- $\beta$ -CD	Sodium phosphate, pH 2.45	0.02% D-enantiomer
Fentoconazole	TM- $\beta$ -CD	Sodium phosphate, pH 3.0	0.2% minor enantiomer, separation of related substances
Galantamine	$\alpha$ -CD	Sodium phosphate, pH 3.0	0.04% minor enantiomer, separation of related substances
L-Hyoscyamine	S- $\beta$ -CD	Sodium phosphate, pH 8.8	0.25% D-hyoscyamine
Ketoprofen	TM- $\beta$ -CD	Sodium acetate, pH 5.0	0.04% ( <i>R</i> )-ketoprofen, stability study of oral solution
Melagatran	DM- $\beta$ -CD	Sodium phosphate, pH 1.8, 10% methanol	0.013% ( <i>S,R</i> )-enantiomer
Methyl dopa	SB- $\beta$ -CD	Sodium phosphate, pH 2.4	0.05% ( <i>R</i> )-methyl dopa, separation of related substances
Propranolol	CM- $\beta$ -CD/DM- $\beta$ -CD	Tris-phosphate, pH 3.0	0.1% ( <i>R</i> )-propranolol
Ropivacaine	DM- $\beta$ -CD	Triethanolamine-phosphate, pH 3.0	0.05% ( <i>R</i> )-ropivacaine, analysis of injection solution
Selegiline	$\beta$ -CD polymer	Tris-phosphate, pH 2.5	0.25% ( <i>S</i> )-enantiomer
Terbutaline	HP- $\beta$ -CD	Sodium phosphate, pH 2.5	0.1% (+)-enantiomer
E-6232	SB- $\beta$ -CD/DM- $\beta$ -CD	Sodium tetraborate, pH 9.2, 10% methanol	0.03% ( <i>R</i> )-enantiomer, separation of related substances

LOD, limit of detection;  $\alpha$ -CD,  $\alpha$ -cyclodextrin,  $\beta$ -CD,  $\beta$ -cyclodextrin; CM- $\beta$ -CD, carboxymethyl- $\beta$ -cyclodextrin; DM- $\beta$ -CD, dimethyl- $\beta$ -cyclodextrin; HP- $\beta$ -CD, hydroxypropyl- $\beta$ -cyclodextrin; TM- $\beta$ -CD, trimethyl- $\beta$ -cyclodextrin, S- $\beta$ -CD, sulfated  $\beta$ -cyclodextrin, SB- $\beta$ -CD, sulfobutyl- $\beta$ -cyclodextrin.

excludes enantiomeric impurities from the scope but guideline Q6A on test procedures and acceptance criteria for new drug substances states that for chiral drugs which are developed as a single enantiomer control of the other enantiomer should be considered in the same manner as for other impurities. In addition to enantiomer analysis, the methods often allow the simultaneous determination of chiral and achiral related substances.

## Bioanalysis

The analysis of drugs, their metabolites, and other exogenous compounds in body fluids and tissue samples is another important aspect of pharmaceutical analysis. Drug metabolism and pharmacokinetics contribute to the optimization of drug therapy in addition to providing fundamental data for drug discovery, development, and regulatory aspects. Because of its high efficiency CE is especially suited in the case of a complex matrix or to address separation problems that cannot be solved by chromatography. Target applications include stereoisomer separations, analysis in the case of very small sample volumes, assays that lack specificity, or methods requiring large amounts of (organic) solvents. In addition, CE has been applied to screening of body fluids and hair for licit or illicit drugs in clinical and forensic samples.

Sample preparation may be absent or include simple liquid handling operations (filtration, centrifugation), removal of endogenous constituents of the matrix (protein precipitation, ultrafiltration), and for selectivity and/or sensitivity enhancement extraction techniques (liquid–liquid extraction, solid-phase extraction) as well as derivatization. Microdialysis samples and urine can be injected onto the capillary in the case of sufficiently high drug concentrations in these samples but the inherent high ionic strength of urine can cause problems and require dilution prior to the injection. MEKC employing SDS often allows the direct injection of protein-containing fluids such as plasma and serum. SDS solubilizes the proteins and prevents their adsorption to the capillary wall, which causes deterioration of the analytical system due to an irreproducible EOF, drifting migration times, and peak asymmetry. A protocol for the direct injection of plasma with subsequent removal of adsorbed protein by rinsing with a SDS solution between runs has been reported. To avoid protein-associated problems protein precipitation by acetonitrile or trifluoroacetic acid can be performed followed by injection of the supernatant upon centrifugation. This operation simplifies the matrix and liberates protein-bound drugs but dilution of the sample occurs. When acetonitrile is used the inherent

electrokinetic solute concentration effect counteracts sample dilution allowing detection limits of the drugs comparable to the direct injection of the sample. Liquid–liquid extraction and solid-phase extraction simultaneously concentrate the solutes by one to two orders of magnitude and increase selectivity by simplification of the sample matrix.

In contrast to the determination of the main component or impurities in drug substances or pharmaceutical formulations where sample concentration is not a major issue, the limited sensitivity of CE may hamper its application to bioanalysis. The lowest detectable amount of compounds using UV detection as the most common detection mode in CE is in the range of  $1\text{--}10\ \mu\text{mol l}^{-1}$ , which is one to two orders of magnitude lower compared to HPLC with UV detection. Increasing the optical path using bubble or Z-shaped detection cells results in a 10-fold improvement, but at some loss of separation efficiency. Employing laser-induced fluorescence detection enhances assay sensitivity by a factor of 100–1000 compared to UV detection and also adds specificity to the assay as not all compounds show fluorescence. However, the approach is limited to analytes that can be excited at the wavelength of the commercially available He–Cd laser (325 nm) or argon-ion laser (488 nm). Hyphenation of CE and MS (CE–MS) yields structural information on drugs and their metabolites. However, while HPLC–MS is more sensitive compared to HPLC with UV detection, CE–MS is less sensitive than UV due to the construction of the currently used CE–MS interfaces employing sheath liquids to increase the CE efflux, which results in a dilution of the sample.

Sample concentration is another way to increase the sensitivity of a method. Besides liquid–liquid and solid-phase extraction protocols, which result in more concentrated solutions in addition to sample cleanup, several electrokinetic concentration techniques can be applied including sample stacking and field-amplified sample injection/stacking. Over 1000-fold sensitivity enhancement compared to hydrodynamic sample injection without stacking has been reported. When acetonitrile has been used for the removal of proteins from plasma, sample injections of up to 50% of the capillary volume become possible. Stacking techniques are also available for MEKC.

Numerous validated achiral and chiral assays of drugs in biological matrices have been reported (Table 5). The assay of lamotrigine was adapted to routine analysis with multilevel internal calibration on different commercial instruments. Evaluation of the calibration and control data from 4 years as well as cross-validation with data from different laboratories clearly demonstrated the suitability of

**Table 5** Examples of the validated capillary electrophoresis methods for the determination of drugs in biological matrices

Drug	Matrix	Extraction	Conditions	Application
Albendazole sulfoxide	Plasma	LLE	Tris-phosphate, pH 7.0, 3% S- $\beta$ -CD	Patient samples
Amphetamine, ecstasy, and analogs	Urine	LLE	Potassium phosphate, pH 2.5, 8.3 mmol l <sup>-1</sup> HP- $\beta$ -CD	Urinary excretion, patients and drug abusers
Cilazapril and metabolites	Urine	SPE	Sodium tetraborate, pH 9.5	Patient samples
Ciprofibrate, ciprofibrate glucuronide	Urine	SPE	Sodium phosphate, pH 6.0, 7.5 mmol l <sup>-1</sup> $\gamma$ -CD	Urinary excretion, stereoselective metabolism
Doxorubicin and metabolite, daunorubicin and metabolite	Serum	LLE/acetonitrile protein precipitation	Sodium phosphate, pH 5.0, 60 $\mu$ mol l <sup>-1</sup> spermine, 70% acetonitrile	Patient samples
Ibuprofen	Plasma	LLE	Triethanolamine-phosphate, pH 5.0, 2% S- $\beta$ -CD	Stereoselective pharmacokinetics
Ketoprofen	Serum	LLE	Triethanolamine-phosphate, pH 5.0, 50 mmol l <sup>-1</sup> TM- $\beta$ -CD	Stereoselective pharmacokinetics
Lamivudine/didanosine/saquinavir	Serum	SPE	N,N-Dimethyloctylamine-phosphoric acid, pH 2.5	Patient samples
Lamotrigine	Serum	Acetonitrile protein precipitation	Sodium acetate, pH 4.5	Patient samples
Mianserin	Plasma	LPME	Triethylamine-phosphate, pH 5.0, 2 mmol l <sup>-1</sup> HP- $\beta$ -CD	Patient samples
Ofloxacin and metabolites	Urine	Direct injection	Triethylamine-phosphate, pH 2.0, 0.3 mmol l <sup>-1</sup> SB- $\beta$ -CD	Urinary excretion, stereoselective metabolism
Quinapril and metabolites	Urine	SPE	Sodium tetraborate, pH 9.5	Patient samples
Tramadol and metabolites	Urine	LLE	Sodium tetraborate, pH 10.1, 30 mg ml <sup>-1</sup> CM- $\beta$ -CD	Urinary excretion, stereoselective metabolism
Trimebutine maleate	Serum, tissue	Acetonitrile protein precipitation	Sodium phosphate, pH 6.0	Pharmacokinetics and tissue distribution
Zaleplon and metabolites	Urine	SPE	Tris-borate, pH 9.4, 50 mmol l <sup>-1</sup> CM- $\beta$ -CD	Urinary excretion

LLE, liquid–liquid extraction; SPE, solid-phase extraction; LPME, liquid-phase microextraction; S- $\beta$ -CD, sulfated  $\beta$ -cyclodextrin; HP- $\beta$ -CD, hydroxypropyl- $\beta$ -cyclodextrin; SB- $\beta$ -CD, sulfobutyl- $\beta$ -cyclodextrin, CM- $\beta$ -CD, carboxymethyl- $\beta$ -cyclodextrin; TM- $\beta$ -CD, trimethyl- $\beta$ -cyclodextrin.

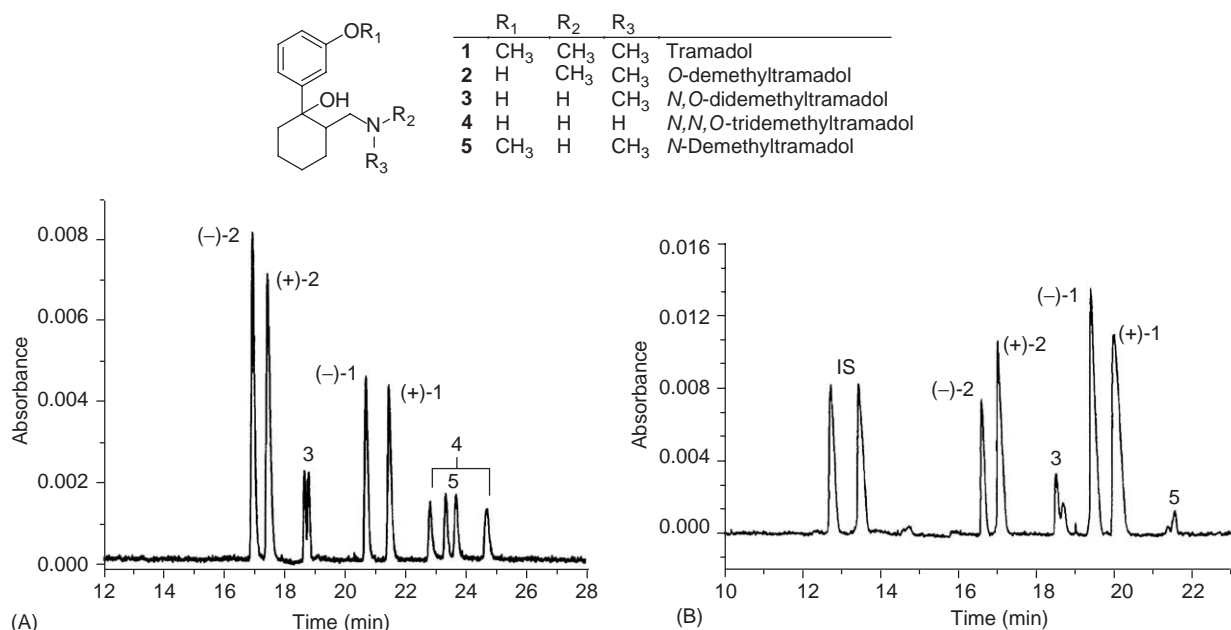

CE-based assays for therapeutic drug monitoring. Despite the fact that HPLC is currently the most widely applied method for drug bioanalysis, CE possesses a clear advantage over HPLC for the chiral analysis of drugs as well as the determination of drugs and their metabolites (Figure 6). The simultaneous analysis of drugs and their phase-II glucuronide and sulfate metabolites is hardly possible by HPLC. Furthermore, CE may be the method of choice when only small sample volumes are available such as blood samples from children and infants or *in vivo* microdialysates.

## Miscellaneous Applications

In addition to the applications described above, CE has been applied to reaction monitoring, drug stability studies, the determination of content release testing from tablets, as well as the analysis of drugs in

cell culture-based transport studies. Furthermore, CE can be employed for the determination of physicochemical properties of compounds such as  $pK_a$  values and lipophilicity. The advantage compared to classical methods is the low consumption of sample and the fact that the compounds do not have to be pure and mixtures of compounds can be utilized. CE is also well suited to study the interactions between ligands and biomolecules such as antibody–antigen interactions or the affinity of drugs to proteins, excipients, or liposomes including stereospecific aspects. Affinity CE, frontal analysis, the Hummel–Dreyer method, and vacancy peak analysis have been applied for this purpose. These analyses do not require pure compounds either and compound libraries can be screened. Moreover, complexation constants have been determined by CE methods.

Current trends in pharmaceutical applications of CE include the use of microchips as well as capillary

**Figure 6** Chiral capillary electrophoresis analysis of tramadol and its metabolites in urine. (A) Separation of reference compounds, (B) analysis of a urine sample collected 6–8 h after oral administration of 100 mg tramadol. The internal standard (IS) was a chiral analog that is also resolved. Experimental conditions: 50/57 cm fused silica capillary, 50  $\mu$ m, 50 mmol l<sup>-1</sup> sodium borate buffer, pH 10.1, 30 mg ml<sup>-1</sup> carboxymethyl- $\beta$ -cyclodextrin, 20 kV, UV detection at 214 nm. (Adapted with permission from Kurth B and Blaschke G (1999) Achiral and chiral determination of tramadol and its metabolites in urine by capillary electrophoresis. *Electrophoresis* 20: 555–563; © Wiley-VCH.)

**Figure 7** Simultaneous chiral separation of three basic drugs. Only about half of the total length of 25 mm of the microchip separation channel was needed to obtain complete resolution in 11 s. Experimental conditions: 25 mmol l<sup>-1</sup> triethylammonium phosphate buffer, pH 2.5, 5% highly sulfated  $\gamma$ -cyclodextrin, UV detection at 200 nm. (Reproduced with permission from Ludwig M, Kohler F, and Belder D (2003) High-speed chiral separations on a microchip with UV detection. *Electrophoresis* 24: 3233–3238; © Wiley-VCH.)

electrochromatography (CEC). CE on microchip devices is a rapidly emerging technology having the potential of analyzing hundreds of samples within minutes. Commercial instruments and different

detection modes as well as the coupling to a mass spectrometer are available. While the premier application of microchip CE still is nucleic acid and protein analysis the determination of peptides and pharmaceutical drugs including bioanalysis and chiral separations by this technique have been reported. **Figure 7** shows the simultaneous chiral separation of three basic drugs on a microchip in 11 s.

CEC is considered a hybrid technique between HPLC and CE combining the high peak efficiency of CE with the high separation selectivity of multivariate stationary phases available in HPLC. The general applicability of CEC to the analysis of drugs including chiral separations has been demonstrated, but it has not yet been implemented in the ‘arsenal’ of pharmaceutical analytical techniques.

## Low-Molecular-Weight Ions

**V Pacáková and K Štulík**, Charles University, Prague, Czech Republic

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Low-molecular-weight (LMW) ions include both inorganic and organic compounds. The main application area of capillary electrophoresis lies in analyses for inorganic and organic anions and cations in environmental samples, in clinical chemistry, pulp and paper industry, process control, industrial applications, explosive residue analysis, biological samples, or drugs and drug intermediates. LMW organic acids are important intermediates or final metabolites of many biochemical pathways in living organisms, as well as degradative metabolites of amino acids, fats, and carbohydrates. LMW organic cations, e.g., quaternary ammonium compounds, are widely used in industry as antiseptic, antistatic, and antimicrobial agents.

In contrast to determinations of organic analytes, where the use of high-performance separations is almost inevitable in complex matrices, inorganic analysis has powerful tools in highly selective and sensitive spectroscopic methods and thus a separation step is often unnecessary. This is especially true for determination of inorganic cations. However, the

selection of methods for determination of inorganic anions is much more limited.

The traditional approach to high-performance separations of LMW ions, ion chromatography (IC), is partially being replaced by capillary electrophoresis (CE) owing to the following main advantages of the CE: a higher separation efficiency caused by a flat local velocity profile in CE running buffers compared to parabolic profiles in IC; a higher speed of analysis caused by the absence of a partition process between the mobile and stationary phases (except for micellar electrokinetic chromatography (MEKC) where the analytes are distributed between a pseudostationary phase and the electrolyte, and capillary electrochromatography employing capillaries packed with stationary phase particles); very small amounts of sample required permit, e.g., an analysis for cations in a single small rat or mice eye lens or analysis for cations and anions present in a single rain drop; very low mass detection limits; low consumption of chemicals (low cost per analysis); relatively simple instrumentation, easy automation, and good tolerance to sample matrix, e.g., to high pH values.

The disadvantages of CE compared to IC include lower sensitivity, higher concentration detection limits, and somewhat poorer reproducibility of qualitative and quantitative data owing to instability of the electroosmotic flow (EOF). IC has so far been developed more extensively. Validated procedures and computer optimization approaches are available

### Introduction

Low-molecular-weight (LMW) ions include both inorganic and organic compounds. The main application area of capillary electrophoresis lies in analyses for inorganic and organic anions and cations in environmental samples, in clinical chemistry, pulp and paper industry, process control, industrial applications, explosive residue analysis, biological samples, or drugs and drug intermediates. LMW organic acids are important intermediates or final metabolites of many biochemical pathways in living organisms, as well as degradative metabolites of amino acids, fats, and carbohydrates. LMW organic cations, e.g., quaternary ammonium compounds, are widely used in industry as antiseptic, antistatic, and antimicrobial agents.

In contrast to determinations of organic analytes, where the use of high-performance separations is almost inevitable in complex matrices, inorganic analysis has powerful tools in highly selective and sensitive spectroscopic methods and thus a separation step is often unnecessary. This is especially true for determination of inorganic cations. However, the

selection of methods for determination of inorganic anions is much more limited.

The traditional approach to high-performance separations of LMW ions, ion chromatography (IC), is partially being replaced by capillary electrophoresis (CE) owing to the following main advantages of the CE: a higher separation efficiency caused by a flat local velocity profile in CE running buffers compared to parabolic profiles in IC; a higher speed of analysis caused by the absence of a partition process between the mobile and stationary phases (except for micellar electrokinetic chromatography (MEKC) where the analytes are distributed between a pseudostationary phase and the electrolyte, and capillary electrochromatography employing capillaries packed with stationary phase particles); very small amounts of sample required permit, e.g., an analysis for cations in a single small rat or mice eye lens or analysis for cations and anions present in a single rain drop; very low mass detection limits; low consumption of chemicals (low cost per analysis); relatively simple instrumentation, easy automation, and good tolerance to sample matrix, e.g., to high pH values.

The disadvantages of CE compared to IC include lower sensitivity, higher concentration detection limits, and somewhat poorer reproducibility of qualitative and quantitative data owing to instability of the electroosmotic flow (EOF). IC has so far been developed more extensively. Validated procedures and computer optimization approaches are available

**Table 1** Equivalent ionic conductivities ( $\Lambda_{eq}$ ) and ionic mobilities ( $m_i$ ) of selected inorganic cations and anions

Analyte	$\Lambda_{eq} (cm^2 \Omega^{-1} mol^{-1})$	$m_i (10^{-4} cm^2 V^{-1} s^{-1})^a$	$m_i (10^{-4} cm^2 V^{-1} s^{-1})$
$NH_4^+$	73.5	7.62	7.62
$K^+$	73.5	7.62	7.62
$Ca^{2+}$	59.5	6.17	6.17
$Mg^{2+}$	53.0	5.49	5.50
$Na^+$	50.1	5.19	5.19
$SO_4^{2-}$	80.0	8.29	8.29
$Cl^-$	76.3	7.91	7.91
$NO_2^-$	71.8	7.44	7.46
$NO_3^-$	71.4	7.40	7.41
$PO_4^{3-}$	69.0	7.15	7.15
$F^-$	55.4	5.74	5.74

<sup>a</sup> Calculated from the equivalent ionic conductivities.

in IC, while routine applications of CE are still less common. The selectivity range in CE is limited, as the selectivity can only be manipulated by the electrolyte composition. CE and IC are complementary rather than competing techniques and exhibit different selectivity; CE is used for separation of those mixtures of anions and cations that are difficult to separate by IC and vice versa.

## Theoretical Consideration

The electrophoretic mobility of an ion,  $\mu_{ep(ion)}$ , can be related to the limiting ionic equivalent conductivity,  $\lambda_{eq}$ , by

$$\mu_{ep(ion)} = \lambda_{eq}/F = q_i/6\pi\eta r_i \quad [1]$$

where  $F$  is the Faraday constant ( $F = 9.6487 \times 10^4 \text{ A s mol}^{-1}$ );  $\lambda_{eq} (cm^2 mol^{-1} \Omega^{-1})$  is related, by the Stokes law, to the charge of the hydrated ion,  $q_i$ , to the dynamic viscosity of the electrolyte,  $\eta (g cm^2 s^{-1})$ , and to the radius of the hydrated ion,  $r_i (cm)$ .

The  $\mu_{ep(ion)}$  values can be calculated from the experimental data, the apparent mobility of the ion,  $\mu_{app(ion)}$ , and the mobility of the EOF,  $\mu_{eo}$ , according to

$$\begin{aligned} \mu_{ep(ion)} &= \mu_{app(ion)} - \mu_{eo} \\ &= (1/t_{m(ion)} - 1/t_{m(eo)})(L_T L_D/V) \end{aligned} \quad [2]$$

where  $t_{m(ion)}$  and  $t_{m(eo)}$  (both in seconds) are the migration times of the ion, and of an EOF marker (an uncharged solute), respectively;  $L_T$  and  $L_D$  (both in centimeters) are the overall capillary length and the length of the capillary to the detector, respectively;  $V$  is the voltage (in volts).

The limiting ionic conductivities and the experimental and calculated electrophoretic mobilities of some anions and cations are compared in Table 1.

The electrophoretic mobilities derived from the limiting ionic equivalent conductivity differ somewhat from the experimentally measured values that are dependent on the composition of the background electrolyte and its pH. Differences in the ionic mobilities as small as  $0.1 \times 10^{-9} m^2 V^{-1} s^{-1}$  are sufficient for the separation of ionic species, provided that the separation is highly efficient. As follows from Table 1, all the ions can be separated except for  $K^+$  and  $NH_4^+$  whose mobilities are identical.

## Optimization of Separation

The running buffer composition is of primary importance to CE selectivity optimization. The buffer contains at least one anion and one cation, and one of these ions should have an adequate buffering capacity. If possible, the EOF should have the same direction as the migration of the analytes to shorten the analysis. The co-ion should have a similar mobility as the analyte to ensure a good peak shape.

The separation is optimized by changing the composition and concentration of the running buffer and by adjusting its pH. As follows from eqn [1], the electrophoretic mobility of ions depends on their charge-to-mass ratio. For weak acids and bases this ratio can be changed by changing the pH in the vicinity of the analyte  $pK_a$ . The effect of the pH on the separation of weak acids can be demonstrated on an example of separation of a high concentration of phosphate (more than  $800 \mu g l^{-1}$ ) from a low concentration of fluoride ( $1 \mu g l^{-1}$ ). Protonation of hydrogenphosphate at a pH of 7 results in its slower migration and leads to an improved separation from fluoride. Another example is a very fast separation of nitrate and nitrite within 10 s at pH 2.5.

An addition of organic solvent to the background electrolyte changes the separation selectivity. This

can be explained by changes in the relative hydration of ions. The organic solvent destroys the hydrated layer and thus changes the effective mass of the ions. Ions such as iodide and chloride, which are difficult to separate in an electrolyte consisting of pyromellitic acid and hexamethonium hydroxide, can be separated after addition of methanol. Organic solvents added to the running electrolyte decrease the EOF; they increase the viscosity and decrease the  $pK_a$  of the silanol groups on the capillary wall and improve the reproducibility of the migration times, with a less noisy baseline. The temperature also affects the selectivity, as it influences both the mobilities and the EOF through a change in the solution viscosity.

### Cations – Direct Analysis

Inorganic cations are smaller and thus have higher charge densities ( $q_i/r_i$  ratios) than most organic ions; therefore, as follows from eqn [1], their electrophoretic mobilities are higher. The problems connected with CE analysis of inorganic cations are caused by small differences in their migration rates (see Table 1), and, similar to the CE analysis of inorganic anions, by their low absorption of ultraviolet (UV) radiation, which complicates detection.

Only the alkali metal ions exhibit large differences in their mobilities and thus can easily be separated within very short times (less than 2 min), if the directions of the EOF and of the cation migration are

the same, toward the cathode. Exceptional is the separation of  $K^+$  and  $NH_4^+$  ions whose mobilities are identical at a slightly acidic pH. Their separation can be attained in alkaline buffers as the ammonium ions are less protonated and their mobility decreases while the  $K^+$  ion mobility is not affected by the pH. Quaternary ammonium ions can be separated in co-electroosmotic mode. However, to have a sufficiently large separation window, the EOF has to be decreased, e.g., by addition of organic solvents.

### Cations – Separation of Complexes

Complexation with auxiliary ligands is used to promote cation separation. Different degrees of complexation lead to different migration times. The migration can thus be influenced by the type and the concentration of the complexing agent, pH, ionic strength, viscosity, etc.

Several complexing agents have been proposed and successfully tested in analyses of cations. Weak complexing agents, such as lactate, phthalate, tartrate, or hydroxyisobutyric acid (for separation of lanthanoids), have been used. For example, 19 alkali, alkaline earth, and rare earth metal ions can be separated in very short time (less than 2 min), using hydroxyisobutyric acid as a complexing agent and an indirect UV detection method (Figure 1). Other complexing agents, such as ethylenediaminetetraacetic acid (EDTA), diaminocyclohexanetetraacetic acid, and 18-crown-6, have also been used.

**Figure 1** Electropherogram of the separation of alkali, alkaline earth, and lanthanide metal ions. Capillary, 36.5 cm, 75  $\mu$ m ID, fused silica; running electrolyte, 10 mmol  $l^{-1}$  UV-Cat-1, 4.0 mmol  $l^{-1}$  HIBA, pH 4.4; separation voltage, 30 kV; detection, indirect UV at 214 nm. Peaks ( $mg\ l^{-1}$ ): 1, Rb (2); 2,  $K^+$  (5); 3,  $Ca^{2+}$  (2); 4,  $Na^+$  (1); 5,  $Mg^{2+}$  (1); 6,  $Li^+$  (1); 7,  $La^{3+}$  (5); 8,  $Ce^{3+}$  (5); 9,  $Pr^{3+}$  (5); 10,  $Nd^{3+}$  (5); 11,  $Sm^{3+}$  (5); 12,  $Eu^{3+}$  (5); 13,  $Gd^{3+}$  (5); 14,  $Tb^{3+}$  (5); 15,  $Dy^{3+}$  (5); 16,  $Ho^{3+}$  (5); 17,  $Er^{3+}$  (5); 18,  $Tm^{3+}$  (5); 19,  $Yb^{3+}$  (5). (Reproduced with permission from Weston A, Brown PR, Jandik P, Jones WR, and Heckenberg AL (1992) *Journal of Chromatography* 593: 289–295.)

In principle, two experimental approaches are taken in the CE analysis of cations, an offline preparation of complexes, prior to the CE analysis, and online complexation in the separation capillary. Their application depends on the stability of the complexes formed.

If weak complexes are rapidly formed, on-capillary partial complexation can be used. A ligand is added to the running electrolyte and a rapid equilibrium between the free metal ions and their complexes is established, with most of the ions present in the free form. Owing to different complexation degrees with various charges on the complexes, the ions have different migration rates. The capillary zone electrophoresis (CZE) mode and an indirect UV photometric detection method are usually employed in this case, as only a small fraction of the cations is complexed.

If the complexes of metal ions with ligands are sufficiently stable under the CE conditions, then off-capillary complexation is preferred. An excess of a strongly complexing agent is added to the sample prior to the CE analysis. On-column UV photometric detection is possible as the fraction of the complexed ions is large. If there is a danger of the dissociation of the complex during the CE analysis, the complexation agent is added to the running buffer in a high concentration. Poor peak shapes can be caused by slow attainment of complexation equilibria in the capillary.

The equilibria of complexation reactions with weakly acidic or basic ligands are influenced by the pH of the running buffer and by the concentration of the complexing agent. The optimum pH for the separation is around the  $pK_a$  of the monoprotic acid. With di- and triprotic acids, the pH must lie between  $pK_{a,1}$  and  $pK_{a,2}$  ( $pK_{a,3}$ ).

The complexing agent must contain suitable binding groups (e.g., carboxyl, hydroxyl), its dissociating sites should not interfere with the complexation equilibrium (they should be located far from the binding groups), and the agent should absorb radiation at wavelengths different from that of the complex.

Cationic, anionic, or neutral metal complexes can be formed offline. In dependence on their structure and charge, they can be separated by CZE or MEKC. An advantage of cationic complexes lies in rapid analyses in CZE due to coelectroosmotic migration. However, the number of metals that can be separated in this mode is limited by a narrow migration window and/or by their similar mobilities. When using MEKC, the polarity can be reversed by an addition of a cationic surfactant to the electrolyte and thus the separation can be improved. Anionic metal complexes, such as those with cyanide, move, during CZE in

uncoated capillaries, to the cathode against the EOF and are detected within an acceptable time due to their rapid migration caused by their small size and/or high charge. Complexes with large ligands move very slowly or not at all. It is then necessary to suppress or reverse the EOF by adding a cationic surfactant or by a suitable coating of the capillary. Neutral complexes can be separated by MEKC.

Separation of cations can be influenced by their interaction with crown ethers, which depends on the sizes of the cation and the crown ether cavity. The concentration of a crown ether in the running buffer also plays a role. The best results have been obtained with 18-crown-6-ether where the selectivity changes were largest. The use of crown ethers makes it possible to separate, e.g., potassium from ammonium. Electrolyte containing  $4 \text{ mmol l}^{-1}$  18-crown-6,  $4 \text{ mmol l}^{-1}$  copper sulfate, and  $4 \text{ mmol l}^{-1}$  formic acid was successfully applied to complete separation of all alkali and alkaline earth cations including ammonium (Figure 2).

**Figure 2** Electropherogram of a mixture of alkali and alkaline earth metal ions. Capillary, 58.5 cm, 75  $\mu\text{m}$  ID, fused silica; running electrolyte,  $4 \text{ mmol l}^{-1}$  18-crown-6,  $4 \text{ mmol l}^{-1}$  copper sulfate, and  $4 \text{ mmol l}^{-1}$  formic acid, pH 4.4; separation voltage, 20 kV; detection, indirect UV at 215 nm. Peaks ( $\text{mg l}^{-1}$ ):  $\text{NH}_4^+$  (20);  $\text{K}^+$  (19.5);  $\text{Na}^+$  (11.5);  $\text{Ca}^{2+}$  (20);  $\text{Mg}^{2+}$  (12.2);  $\text{Sr}^{2+}$  (43.8);  $\text{Li}^+$  (3.5);  $\text{Ba}^{2+}$  (68.7). ## Anions

While cations can be analyzed directly in CE, the elution of anions in bare silica capillaries requires reversion of the EOF. The EOF can be changed by addition of cationic additives to the running electrolyte, by changing the concentration of the running electrolyte, or by a chemical modification of the capillary walls. Cationic surfactants are mostly added to reverse the EOF in analyses of anions. At concentrations below the critical micelle concentration, hemicelles are formed at the capillary wall that reverses the EOF. If anions interact with a monomeric surfactant present in the electrolyte, then their electrophoretic mobilities are influenced through ion association. The most common cationic surfactants used are, e.g., tetrabutylammonium, dodecyltrimethylammonium, tetradecyltrimethylammonium, and cetyltrimethylammonium (CTA) bromides or hydroxides, hexadimethrine, and hexamethonium hydroxides. Higher concentrations of additives lead to longer migration times owing to the formation of equilibrium ion-pairs. Differences in the selectivity allow complex samples to be analyzed by properly selecting the EOF modifier concentration and thus increasing the weak acid anion migration times.

Another possibility for EOF modification is coating of the capillary walls with cationic-soluble polymers. A net positive charge is then formed at the capillary walls. Reducing the EOF, e.g., by coating the capillary walls with silane, is sufficient for attaining sufficiently short analysis times for some anions. The EOF can also be modified by using capillaries made of materials other than fused silica, e.g., of polypropylene.

## Detection Modes

Detection in CE takes place directly on the separation column. The UV/Vis photometric detection is most common in capillary electrophoresis, as it is simple and reliable. The problems connected with the detection of LMW ions are caused by their low absorption in the UV region. Therefore, direct UV detection is only applicable to a few inorganic anions, e.g., to nitrate, sulfide, nitrite, iodide, bromide, and thiocyanate (for example, a detection limit of  $10 \mu\text{g l}^{-1}$  has been attained for sulfide in waste water using direct UV detection at 229 nm). LMW carboxylic acids can be detected at low wavelengths (200 nm and below).

Direct UV/Vis or fluorescence detection is often employed in analyses of cations after their complexation, provided that the ligand contains a chromophore or a fluorophore. Several metal ions, e.g.,  $\text{Fe}^{2+}$ ,  $\text{Fe}^{3+}$ ,  $\text{Co}^{2+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Cu}^{2+}$ ,  $\text{Cd}^{2+}$ , form complexes with cyanide. Analogously,  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  form complexes with *o*-phenanthroline in the presence of EDTA and  $\text{Au}^{3+}$  with chloride and these complexes can be detected spectrophotometrically. 8-Hydroxyquinoline-5-sulfonic acid forms fluorescing complexes with metals. Dithizone sulfonate complexes have been used in determination of traces of inorganic mercury. 4-2-(Pyridylazo)resorcinol (PAR) forms colored complexes with  $\text{Cu}^{2+}$ ,  $\text{Pb}^{2+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Cd}^{2+}$ ,  $\text{Fe}^{2+}$ , and  $\text{Fe}^{3+}$ , arsenazo I forms complexes with  $\text{Ba}^{2+}$ ,  $\text{Sr}^{2+}$ ,  $\text{Ca}^{2+}$ , and  $\text{Mg}^{2+}$ , arsenazo III has been recommended for separation of the lanthanoids and  $\text{U}^{6+}$ , sulfonoazo III for the determination of  $\text{Ba}^{2+}$  and  $\text{Sr}^{2+}$ . Detection limits of  $10^{-7} \text{ mol l}^{-1}$  have been

**Figure 3** Ionic mobilities of analytes and absorbing co-ions.

attained, using PAR complexes with the transition metals.

Indirect UV or fluorescence detection, based on charge displacement of an absorbing co-ion, is nearly universal. A disadvantage of indirect detection is a high background absorbance and thus a high noise and a limited linear dynamic range. UV absorbing anions or cations are added to the running electrolyte. For indirect UV detection, the co-ion should strongly absorb in the UV region and should have a mobility similar to those of the analytes to ensure optimum separation and peak shape. The EOF should have the same direction as the analyte migration to improve the speed of analyses. Cupric sulfate, imidazole, histidine, 4-methylbenzylamine, or creatinine are employed in analyses of cations while chromate, pyromellitic acid, phthalate, *p*-aminobenzoate, or molybdate in analyses of anions. **Figure 3** helps in the selection of a suitable UV-absorbing ion for indirect analysis of cations and anions. The chromate anion matches the mobilities of small anions while phthalate or benzoate is suitable for large anions. Molybdate has been shown to be a better visualization agent than chromate, yielding improved peak shapes because the molar absorptivity of molybdate is higher than that of chromate. Detection limits in ppb region have been obtained using a running electrolyte containing chromate, with a time of analysis of 3 min. *p*-Aminobenzoate has been found useful for simultaneous determination of low mobility organic and high mobility inorganic anions. The separation has been facilitated by an addition of a barium salt. So far the best separation of anions with indirect UV detection has been attained in the IonPhor PMA electrolyte buffer consisting of  $2.5 \text{ mmol l}^{-1}$  pyromellitic acid,  $6.5 \text{ mmol l}^{-1}$  NaOH,  $0.75 \text{ mmol l}^{-1}$  hexamethonium hydroxide, and  $1.6 \text{ mmol l}^{-1}$  triethanolamine, with a pH of 7.7. Anionic chromophores (benzoate, anisate) and cationic buffers (Tris, ethanolamine) have been tested for simultaneous detection of nonabsorbing anions and cations.

A CE method with indirect UV detection has been validated for eight anions and two electrolyte systems: pyromellitic acid + hexamethonium hydroxide and chromate + TTAB. The detection limits are between 1 and  $3 \text{ mg l}^{-1}$ , the repeatability and reproducibility of the measurement differ for different compounds and amounts to 5%, except for fluoride and phosphate. Linear calibration curves have been obtained within a concentration range between 1 and  $10 \text{ mg l}^{-1}$ .

Conductivity detection (CD) is a nearly universal bulk property detection mode for small ions and, similar to detection in IC, both nonsuppressed and

**Figure 4** Electropherogram of the analysis of cationic impurities in drug Carbetocin with conductivity detector. Capillary, 70.0 cm,  $50 \mu\text{m}$ , fused silica; running electrolyte,  $30 \text{ mmol l}^{-1}$  histidine,  $30 \text{ mmol l}^{-1}$  2-morpholinoethan-sulfonic acid; separation voltage, 30 kV; injection, hydrodynamic, 20 mbar for 6 s; detection, conductometric. Peaks: 1,  $\text{K}^+$ ; 2,  $\text{Ba}^{2+}$ ; 3,  $\text{Ca}^{2+}$ ; 4,  $\text{Mg}^{2+}$ ; 5,  $\text{Na}^+$ ; 6,  $\text{Li}^+$ . (Kindly provided by Dr. I. Jelínek from our Department.)

**Figure 5** Trace determination of inorganic and organic anions in pure water, after an electrophoretic enrichment at 5 kV for 45 s with an addition of  $75 \mu\text{mol l}^{-1}$  octanesulfonate to the sample. Capillary, 60 cm,  $75 \mu\text{m}$ , fused silica; running electrolyte,  $10 \text{ mmol l}^{-1}$  sodium chromate and  $0.5 \text{ mmol l}^{-1}$ , pH 8, UV detection at 254 nm. Anions (concentration in  $\text{mg l}^{-1}$ ): 1, chloride (3.5); 2, sulfate (4.8); 3, nitrate (6.2); 4, oxalate (5); 5, fluoride (1.9); 6, formate (5); 7, phosphate (3.2); 8, acetate (5); 9, propionate (5). suppressed CDs are used. There are more options for the selection of the running electrolyte in combination with CD. The co-ion must have a substantially different conductivity. In nonsuppressed

**Figure 6** Determination of inorganic and organic anions with direct conductivity detection. Capillary, 60 cm, 50  $\mu\text{m}$ , fused silica; running electrolyte, 50  $\text{mmol l}^{-1}$  2-*N*-cyclohexylamino-ethane-sulfonate, 20  $\text{mmol l}^{-1}$  LiOH, 0.03% Triton X-100; separation voltage, 25 kV; injection, hydrodynamic, 25 mbar for 12 s; the EOF was modified by preflushing the capillary with a 1  $\text{mmol l}^{-1}$  CTAB. Anions (concentration in  $\text{mg l}^{-1}$ ): 1, bromide (4); 2, chloride (2); 3, hexacyanoferrate (7); 4, nitrite (4); 5, nitrate (4); 6, sulfate (4); 7, azide (2); 8, oxalate (3); 9, molybdate (5); 10, tungstate (6); 11, 1,2,4,5-tetracarboxylic acid (7); 12, fluoride (1); 13, tartrate (5); 14, selenite (10); 15, phosphate (4); 16, citraconate (5); 17, glutarate (10); 18, phthalate (10); 19, carbonate (4); 20, acetate (10); 21, chloroacetate (10); 22, ethanesulfonate (20); 23, dichloroacetate (15); 24, propionate (15); 25, propanesulfonate (20); 26, crotonate (15); 27, butanesulfonate (20); 28, butyrate (15); 29, toluenesulfonate (15); 30, penatenesulfonate (20); 31, valerate (15); 32, hexanesulfonate (20); 33, caproate (15); 34, heptanesulfonate (20); 35, morpholineethanesulfonate (35); 36, octanesulfonate (20); 37, D-gluconate (40).

CD, low mobility buffers with higher ionic strengths provide an extended linearity and improve preconcentration by sample stacking.

In comparison with indirect UV detection, the sensitivity of CD is  $\sim 10$  times greater. The linear dynamic range extends over three concentration decades and the reproducibility of the migration times, peak area, and height is very good. A borate buffer (2  $\text{mmol l}^{-1}$ , pH 9.2) combined with suppressed conductivity detection provides good peak shapes owing to a close match of the borate mobility with those of the separated anions and meeting the principal condition of suppressed CD, i.e., the suppression leads to a weakly conducting species. Additives, such as barium ions, decrease the EOF and the migration velocity of high mobility anions, so that

they can be analyzed simultaneously with organic anions. Detection limits within a range of 1–10 ppb have been reported with suppressed conductivity detection.

Similar to CE analysis of anions, on- or end-column CD can be used for cations, with a sensitivity  $\sim 10$  time greater than that of the indirect UV detection. CD is a nearly universal bulk property detection mode for small ions. Inorganic or organic buffers with low conductivities, e.g., borate or MES-histidine, and higher ionic strengths are used when employing conductivity detection. **Figure 4** depicts a determination of cationic impurities ( $\text{K}^+$ ,  $\text{Ba}^{2+}$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Na}^+$ , and  $\text{Li}^+$  ions) in the drug Carbetocin using a MES-histidine buffer with conductivity detection. Contactless conductivity detection has

been suggested for analysis of  $\text{Rb}^+$ ,  $\text{K}^+$ ,  $\text{Na}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Mn}^{2+}$ ,  $\text{Cd}^{2+}$ , and  $\text{Li}^+$  cations, with a detection limit of  $\sim 1 \times 10^{-4} \text{ mol l}^{-1}$ . On-capillary cells combining contactless conductivity and UV/Vis detection improve the identification potential in separations of LMW ions.

CE-MS has been used in analyses of anions and cations as a method simultaneously providing positive identification and quantitation. CE-ESI MS is particularly well suited for analyses of quaternary ammonium salts. Speciation analysis of As can be carried out using a CE-ICP-MS. Problems in interfacing the ICP-MS detection to CE are associated with low flow rates and small samples analyzed. Detection limits in ppb region can be attained, using postcapillary hybridization prior to ICP-MS.

## Preconcentration Techniques

Sample preconcentration is usually necessary for analyses of highly dilute solutions, e.g., for separations of anions in deionized water or their determination in the presence of a large excess of a matrix component.

Isotachophoretic enrichment by electrostacking at the sample-buffer interface can be used. The sample matrix can assist in the stacking process by functioning as the leading or terminating electrolyte. The co-ion of the running electrolyte has to be chosen so that the analyte mobilities are between those of the ions of the electrolyte and the matrix. Limits of detection lower than  $50 \text{ nmol l}^{-1}$  have been attained in the simultaneous analysis of inorganic and organic anions in rain water when enriching by sample stacking with a dynamic injection. This preconcentration method permits determination of inorganic anions in the presence of a fluoride matrix up to an analyte-matrix ratio of  $1:6 \times 10^6$ .

Preconcentration with the electrokinetic injection can be used for nonionic matrices. With long injection times, the ionic components are preconcentrated at the expense of the nonionic interferents. The EOF has the direction opposite to the migration of the analytes. The matrix effects caused by ionic components can be decreased by suppressing their dissociation by a pH change, thus enriching the analytes by up to two orders of magnitude. The choice of the amount injected is influenced by the analyte mobilities, the magnitude of the EOF, and the sample and buffer ionic strengths. The reproducibility of the electrokinetic injection is poorer than that of the dynamic pressure injection and strongly depends on the running electrolyte ionic strength. Internal standards are usually added to improve the accuracy

and precision. A trace determination of some inorganic and organic anions in deionized water after electrokinetic enrichment with indirect UV detection is shown in Figure 5. A number of applications can be found in the references under Further Reading. An electropherogram of inorganic and organic anions with direct conductivity detection is given in Figure 6.

### Introduction

Capillary electrophoresis (CE) is now emerging in environmental analysis as an advantageous tool because of its features such as higher separation efficiency, shorter analysis times, simplicity with regard to instrumentation, less consumption of expensive reagents and toxic solvents, field-screening capabilities, and microminiaturized format, e.g., CE on a chip. The originally reported CE limitation of inadequate sensitivity for environmental analysis, as a result of the small sample volumes typically injected ( $\sim 1$ – $10$  nl), has been overcome by off- and on-column trace enrichment schemes and improvements in sensitivity of detectors. CE can offer to the environmental chemist separation of compounds with a gas chromatography (GC)-like efficiency, and the ability of liquid chromatography (LC) to determine components that are thermally degradable or nonvolatile, without the derivatization of the analyte. Current CE methods are robust enough to provide valuable contributions to environmental assessment and their different selectivity make them complementary to LC and GC. In this article, the role of electrophoresis in environmental chemistry is introduced, followed by an examination of how CE is used in those environmental applications (sample treatment, on-column preconcentration procedures, CE modes of operation, and detectors).

### Types of Environmental Applications

The growing importance of this technique in the field of environmental analysis is emphasized by the appearance of first CE methods that are applicable to routine problems such as the determination of polar volatiles, most semivolatiles, nonvolatiles (e.g., herbicides), inorganic cations, inorganic anions, and natural organic matter (NOM). Most of the compounds determined by CE in different environmental matrices are shown in Table 1.

CE has been applied to anion and cation analysis during the last 15 years. This technique constitutes a viable alternative to ion chromatography. The United States Environmental Protection Agency (US EPA) has already approved a CE method for determining hexavalent chromium (in Region VII) and is currently

considering this technique to be included in the methods compendium SW-846 as an anion analysis method. This technique is appropriate for the analysis of dissolved inorganic anions in drinking water, ground water, surface water, and wastewater. CE has the impressive capability of separating inorganic ions. As an example, several metal cations, including 13 lanthanides, can be separated in only 6 min using lactate to partially complex the metal ions (Figure 1).

In environmental chemistry, the identification and quantification of element species are becoming increasingly important. It has been noted that the distribution, bioavailability, accumulation, and toxicological properties of heavy metals are strongly dependent on the chemical binding forms in which they occur in natural compartments. Since separation in CE is mainly governed by differences in charge-to-size ratio of the analyte, the technique is extremely powerful in discriminating the speciation pattern of redox-sensitive elements and organometallics. This has been proved for various environmentally significant elements such as mercury, arsenic, selenium, tellurium, antimony, lead, iron, chlorine, sulfur, and nitrogen (Figure 2).

The CE analysis of organic contaminants has caught the attention of analytical chemists because there are hundreds of these compounds that are released in the environment as a consequence of human activity. Many of them are considered, owing to their toxicity, as priority pollutants by the US EPA and the European Union (EU). The groups of compounds that have received most attention are pesticides, phenols, nitroaromatics, and other chemical warfare-related compounds, amines, aromatic sulfonic acids, carboxylic acids, endocrine disrupting compounds, phthalate esters, carbonyl, and dyes. Because of analyte preconcentration and stacking injection techniques, CE has become competitive in trace analysis and it is now being applied to environmental real matrices (Figure 3).

The chiral resolution of environmental pollutants by CE is a very interesting feature, since one of the chiral isomers may be more toxic than the other. In addition, biological transformation of the enantiomers is many times stereoselective, and, therefore, their uptake, metabolism, and excretion can be different. Besides, CE has also been utilized to separate the structural isomers of various toxic pollutants such as phenols, polyaromatic hydrocarbons, etc.

The term soil organic matter represents the organic part of soil, which includes high-molecular-mass organic material (proteins, etc.), small molecules

Alkylphosphonic acids and their degradation products	Aquatic samples (surface water and soil solutions)
<b>Natural organic matter</b>	
Humic acids	Aquatic samples (river water), soil (Antarctic soil)

(amino acids, sugars, etc.), and humic substances (HS) (humic acids, fulvic acids, and humin). HS are complex, multicomponent mixtures of natural products, which result from the decay of plant and animal residues. They are ubiquitous in soil, water, and sediment, comprising ~40–60% or more of the dissolved organic carbon in natural water systems. HS play an essential role in determining the fate of environmental contaminants because of their ability to bind, sequester, and transport a wide range of organic compounds, heavy metals, and radionuclides.

The overriding feature of HS is their intrinsic heterogeneity of structure and conformation. Researchers have attempted to solve the structural puzzle of these materials by using mass spectrometry (MS) and nuclear magnetic resonance, but have simply shown that HS are complex mixtures of compounds with no defined structure or molecular mass. Resolution of HS has been equally challenging. Their charged nature renders them separable using CE, although they tend to migrate together in a single, broad peak (Figure 4).

A variety of environmental matrices have been analyzed for the characterization of inorganic compounds, organic contaminants, and NOM. The measurement of inorganic cations and anions in various airborne samples (ambient air, aerosols, and dust) and wet deposition (rain and snow) continues

**Figure 3** Single wavelength (240 nm) electropherogram of (A) an extract tomato blank and (B) extract of fortified tomato blank with 10 compounds at the 0.5 mg per kg level. being the subject of many studies. Much of the work on atmospheric samples involves the determination of common inorganic anions (Cl<sup>-</sup>, NO<sub>3</sub><sup>-</sup>, and SO<sub>4</sub><sup>2-</sup>), and cations of interest (alkali and alkaline earth metal and ammonium cations). Atmospheric samples that are characterized by low ionic strength provide very low detection limits under stacking conditions. Innovative applications of CE techniques in atmospheric science are the direct measurement of ionogenic atmospheric gases, and the determination of soluble gases and organic vapors (phenolic compounds and pesticides).

Recent applications of CE have been focused on natural aquatic samples. Water constitutes a clean environmental substratum suitable for direct injection in CE. The most intensively analyzed samples have been drinking, mineral, surface, ground, and sea waters. A number of methods have been described that yield detection limits for a variety of analytes below the concentrations at which they are present in real samples: inorganics, organometallics, surfactants, polycyclic aromatic hydrocarbons

(PAHs), dyes, amines, aromatic and aromaticsulfonic acids, pesticides, phenols, endocrine disrupting compounds, and NOM.

A difference between seawater and most other natural aquatic sources is its high ionic strength. This often complicates direct CE analysis. Another serious problem is due to large differences in concentrations between matrix components, such as sodium or chloride, and minor cationic and anionic constituents. One way to solve seawater matrix effects on separation and detection is sample dilution, but compounds present at lower concentrations can be diluted below the detection limits.

From an environmental point of view, analysis of waste waters is of great importance for characterizing their potential danger, and, in the case of emission to the environment, for detecting their spread and/or their origin. As for seawater, the matrix of waste water is complex and usually requires a treatment prior to analysis. Numerous examples of CE applications to different typologies of waste waters are reported in the current literature. CE was relevant to determine inorganics in samples of many different industrial processes (leather industry, pulp

and paper industry, extraction and precipitation of alumina from bauxite, and metal processing plants) and to the simultaneous identification of organic and inorganic anions in dumping sites. CE was also used in the control of relatively pure waste waters, such as the water from power or water purification plants, which requires control of inorganics, surfactants, PAHs, pesticides, phenols, and endocrine disrupting compounds at very low levels.

Determination of contaminants in sediments and soils by CE has received relatively little attention compared to the profusion of data concerning water analysis. This is probably related to the complexity of the sample matrices, and to the analytical difficulties involved in bringing the analytes into solution. CE is applied to anion and cation analysis in soils including sulfate analysis – widely used as an indicator of soil fertility – and separation of lithium, potassium, magnesium, barium, zinc, lead, lanthanum, samarium, europium, and dysprosium cations. This technique is also promising for determining organic contaminants associated with soil, such as PAHs, dyes, organo-tin compounds, and pesticides. Metal speciation is an unsettled issue in soil analysis

to provide relevant information regarding contamination and bioavailability of toxic metals. CE has been used to separate platinum species (many of them are potent sensitizers, even in very small doses), alkyl-lead and alkyl-tin compounds (widely used in industry, known to be potential causes of environmental pollution) and inorganic and organic mercury. Finally, the most important challenge to the pedologists is the characterization of the organic matter in soil and to understand better the humification process. CE seems to be an essential tool.

CE procedures for the analysis of samples of biological origin have also been reported. Although the number of published methods remains small, a representative range of pesticides in various fruits, vegetables, and grains; dyes (used as fruit fly toxicants) in coffee cherries and green roasted beans; heterocyclic aromatic amines in fried beefsteak, meat

extract, and baked salmon; biogenic amines in soy sauce, and fishery products; and methyl mercury in fish, can be determined by CE.

## CE Modes in Environmental Analysis

### CE Separation

A variety of CE modes are suitable to separate inorganic species, organic contaminants, and NOM, depending on the particular problem to be solved. Table 2 provides a comparison of the different CE modes and approaches applied to solve most environmental analytical problems.

The basic CE relies on the mobility of charged species in an electric field. The uncoated fused-silica capillary is filled with some type of electrolyte solution, known as the running buffer or background

**Table 2** Applications of different CE approaches to solve the separation problems in environmental applications

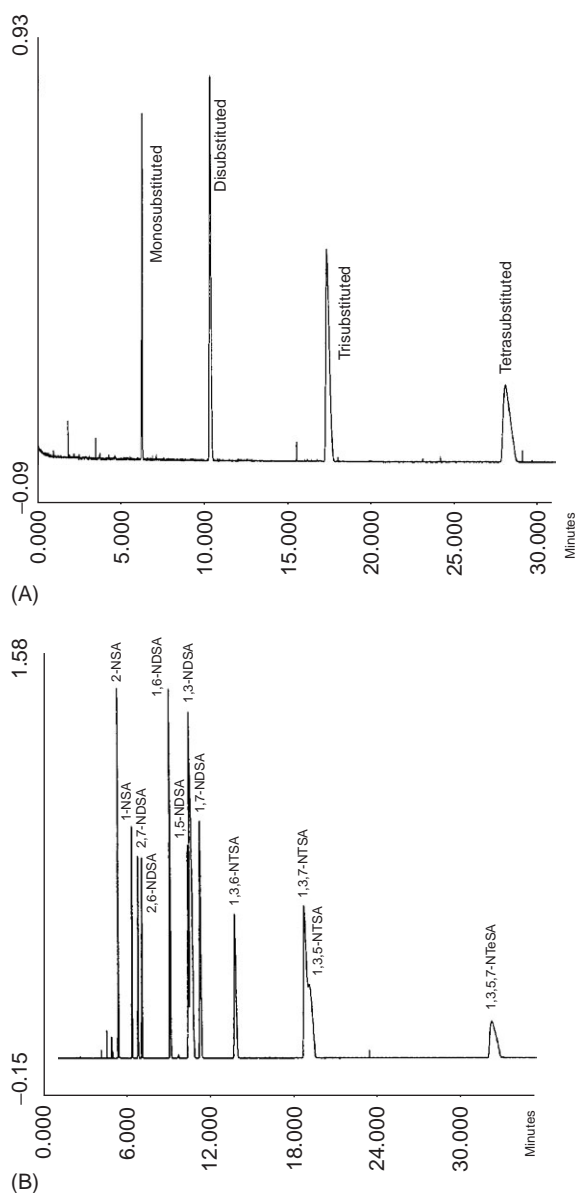

<i>Application</i>	<i>Problem</i>	<i>Solution</i>
Ionizable species	Lack of resolution	Improvement of separation by adjusting the buffer pH, alteration of the buffer ionic strength, and addition of organic solvents as methanol, 2-propanol, or acetonitrile
Inorganic cations	Differences in mobilities between cations of similar $m/z$ are often not sufficient for separation	Addition of weak complexing reagent to the sample and/or to the BGE gives complexed species. Complexed ligands are lactate, HIBA, crown esters, EDTA
Positively charged species	Strong adsorption of these substances at the inner surface of the silica capillary	Addition of organic modifiers in large amounts, the use of coated capillaries, or separation in absolute NACE
Negatively charged species	EM of the anionic species is close to or greater than EOF mobility	Reversal EOF mode by acidic pH or by addition of cationic surfactants at concentrations below the CMC that form a positively charged layer on the inner wall of the capillary
Cations and anions simultaneously	Simultaneous determination of high mobility inorganic anions and cations in a single run is difficult, especially with low EOF because they migrate in opposite direction	Transform cations into negatively charged complexes with EDTA, NTA, or PDC Use of one capillary, the sample is injected in both ends, and the detector is placed in the middle of the capillary
Ionizable species	Species that have very small charge-to-mass differences	NACE
Enantiomers	Chiral complexing reagents are required	Addition of CD to the BGE
Organic contaminants	Differences in mobilities between compounds of similar $m/z$ are often not sufficient for the separation	NACE
Polar and neutral solutes	Solubilization and mobility of neutral compounds	Formation of pseudostationary phase by MEKC or by MEECC Utilization of a stationary phase by CEC
Very hydrophobic analytes	Low solubility in the aqueous phase. They are totally incorporated into the micelle and cannot be separated	Addition of CDs to achiral surfactant solutions, which can include hydrophobic compounds changing the apparent distribution coefficients between the micelle and the non-micellar phases
Trace-level hydrophobic analytes	Unacceptable detection limits without preconcentration	Concentration by RMMEKC characterized by anionic micelles moving faster than the EOF

electrolyte (BGE). An electric field is applied to the capillary, and then cations go to the cathode whereas anions migrate to the anode. However, in the most conventional conditions, there is an electroosmotic flow (EOF) of the BGE induced by the negative ionization of the silica groups on the inner surface of the capillary. The excess cations in the diffuse double layer migrate toward the cathode, with their hydrogen shell, thus generating a net movement of liquid toward the negative electrode. This waterflow has a flat profile. As a consequence, the EOF provided high separation efficiencies compared to pressure-driven flow. It is the dynamic force of CE that will move all analytes toward the negative electrode (cathode). This basic mode has been used for determining inorganic ions, surfactants, PAHs, photoactive dyes, aromatic and heterocyclic aromatic amines, aromatic acids, naphthalene sulfonates, phenols, haloacetic acids, metallo-cyanide complexes, ethylenediaminetetraacetic acid (EDTA), alkylphosphonic acids, humic acids, and several classes of pesticides such as triazines, chlorophenoxyacids, sulfonylureas, and organo-tin compounds. BGE solutions can be either aqueous or nonaqueous, and can also contain additives such as cyclodextrin (CD) or polymers.

Nonaqueous capillary electrophoresis (NACE) involves the separation of analytes in a medium composed of organic solvents. The viscosity and dielectric constants of organic solvents affect both sample ion mobility and the level of EOF. The changes in separation selectivity in nonaqueous conditions contribute to a better separation of some substances that have very small charge-to-mass differences in aqueous phases (linear alkylbenzene sulfonates, or triazines). Further adsorption on the capillary wall and/or ion interactions, which cause solute precipitation (e.g., anionic surfactants with cations), can be avoided using NACE.

CE offers unsurpassed efficiency in chiral separations. As enantiomers have identical electrophoretic mobilities, some chiral complexing reagents must be added to the separation buffer to form diastereomeric complexes in dynamic equilibrium. One of the most popular procedures is the addition of CDs to the separation buffers. The outstanding chiral separation ability of the CE systems is accredited for phenoxy acid herbicides and triazole fungicides, which possess at least one chiral center. Addition of CDs can also be used for separating positional isomers as complex mixtures of unsubstituted naphthalene mono- to tetrasulfonic acids by CE (Figure 5).

Electrokinetic capillary chromatography (ECC) is another CE mode based on a combination of electrophoresis and interactions of the analytes with

**Figure 5** Separation of a mixture of naphthalenesulfonic acids (A) without CD and (B) with mixed  $\beta$ - and  $\gamma$ -CDs at a concentration of  $0.005 \text{ mol l}^{-1}$  each. Capillary, 75 cm (60 cm to detector)  $\times$   $50 \mu\text{m}$  ID uncoated fused-silica. Borate buffer,  $0.025 \text{ mol l}^{-1}$  (pH 9); voltage  $+25 \text{ kV}$ ; injection at 25 mbar, 0.1 min. Detection UV, 230 nm; capillary temperature  $35^\circ\text{C}$ ; overpressure  $2500 \text{ Pa}$  applied across the capillary (Reprinted with permission from Fisher J, Jandera P, and Stanek V (1997) Effects of the working electrolyte (cyclodextrin type and pH) on the separation of aromatic sulfonic acids by capillary zone electrophoresis. *Journal of Chromatography A* 772: 385–386; © Elsevier.)

additives (e.g., surfactants), which form a secondary phase moving at different velocities.

Micellar electrokinetic chromatography (MEKC) is a special and widely used case of ECC methods based on the differences between interactions of analytes with micelles present in the separation buffer,

which can easily separate charged and neutral solutes with either hydrophobic or hydrophilic properties. Micelles are formed by adding a surfactant, at a concentration above its critical micelle concentration (CMC), to the resolution buffer. The partition of analytes in and out of the micelles mimics reversed-phase LC conditions. The most striking feature is the resolution of MEKC, which is more likely to separate complex mixtures than CE. The most widely used surfactant has been SDS, but bile salts including sodium cholate, sodium deoxycholate, cetyltrimethylammonium bromide (CTAB), tetradecyltrimethyl ammonium bromide (TTAB), and others are also used frequently.

Most recently, a special technique of ECC, microemulsion electrokinetic chromatography, where a microemulsion is employed as dispersed phase, has been used for determining endocrine disrupting compounds.

Capillary electrochromatography (CEC) is a rapidly evolving hybrid technique between LC and CE. In essence, a voltage is applied across CE capillaries filled with an LC packing that generates two effects: differential partitioning and electrophoretic migration of the solutes during their transportation toward the detector. Generally, carrier electrolytes employed contain high levels (40–80%) of organic solvents such as methanol or acetonitrile. Exceptional resolution of water-insoluble and neutral solutes is readily achieved in CEC whilst these separations are more difficult to achieve by CE or LC. CEC has much latent potential to be exploited in the area of environmental analysis, especially those concerning the use of new materials, as molecularly imprinted polymers and immunosorbents, as stationary phases.

Future trends in the separation area will include translation of all these methods to microchip format, which promises to lead the next revolution in chemical analysis. MEKC and isotachopheresis, a CE separation technique in a discontinuous buffer system, have already been adapted to microchips and applied to assay herbicides, biogenic amines, and ions. Microchannels on a chip-like structure are likely to be exploited more frequently in CE after further development of nanotechnology because it results in extremely rapid separations that consume only picoliter sample volumes and introduce the possibility of merging sample preparation and analysis in a single device.

### Sample Enrichment Procedures

**Offline preconcentration procedures** The analysis of organic and inorganic compounds in environmental matrices presents several difficulties that are

common to all analytical separation techniques. These problems include the presence of a large number of compounds in the matrix, which leads to difficulties in resolving the analytes of interest. The occurrence of substances such as proteins, organic matter, or surfactants can modify the capillary characteristics, and, together with the low analyte concentrations, complicate the detection. Therefore, quite often a sample pretreatment is required. Typical sample preparations include solid-phase extraction (SPE) or liquid–liquid extraction (LLE). A further concentration is achieved by evaporating the organic solvent and reconstituting the sample in a smaller volume.

SPE and LLE can be used to extract the analyte from a matrix with some degree of specificity. Selectivity is obtained by adjusting the nature of the solid phase (in SPE) or the composition of extracting or eluting solvents. As a consequence of this selectivity, there is not one general extraction method for all the compounds determined in environmental matrices. Information on the different extraction procedures applied is given in Table 3. SPE or LLE present the advantage of preconcentrating the analytes, often 10–100 times.

Inorganic elements can often be released from solid matrices by water extraction, occasionally at elevated temperatures, or by homogenization in water followed by centrifugation, both procedures guaranteeing a high recovery without denaturation. In some cases, however, complete sample dissolution is required. The system of election is the closed-vessel microwave assisted acid digestion because this type of procedure has much lower risk of contamination and enhances the rate of decomposition. The extraction of organometallic compounds requires a partition step with an organic solvent immiscible with water.

The common practice to extract NOM from soils is to treat the sample with a strong base (sodium hydroxide) that solubilizes the humic materials.

Although LLE is effective in extracting many organic contaminants, it has been replaced by SPE, which has become the most powerful technique available for rapid and selective extraction of organic contaminants. SPE combines extraction and preconcentration of analytes from a liquid phase by adsorption on solid material, followed by desorption with a small quantity of an organic solvent providing extraction, cleanup, trace enrichment, and exchange of analyte environment for subsequent analysis in a unique step. Most of the SPE applications are based on the extraction using disposable cartridges or disks packed with C<sub>18</sub>-bonded silicas, porous graphitic carbon, or polymers (polystyrene–divinylbenzene; poly(divinylbenzene-co-*N*-vinylpyrrolidone) Oasis<sup>®</sup>

**Table 3** Sample preparation methods for capillary electrophoresis in environmental analysis

<i>Sample preparation</i>	<i>Analytes</i>	<i>Matrices</i>	<i>Remarks</i>
Homogenization in water and further filtration or centrifugation	Inorganic analytes and pesticides (dithiocarbamates, glyphosate, and metabolites)	Soil, sediment, and particulate matter; and biological material	Incomplete sample dissolution
Microwave-assisted acid digestion	Inorganic analytes	Soil, sediment, and particulate matter	Losses and decomposition of some analytes
Extraction with organic solvent and partitioning	Organometallic compounds and pesticides	Soil, sediment, and particulate matter; and biological material	High consumption of expensive and toxic organic solvents
Solid-phase extraction (SPE)	Endocrine disrupting compounds; surfactants; dyes; aliphatic and aromatic amines; pesticides; phenols; haloacetic acids; cyanide; EDTA; and alkylphosphonic acids	Aquatic samples (drinking, mineral, and tap water, surface water, seawater, wastewater, soil solutions); soil, sediment, and particulate matter; and biological material	Before SPE can be used with solid matrices (e.g., biological materials or soil), homogenization with a hydroalcoholic solvent and further filtration or centrifugation are required
Solid-phase microextraction (SPME)	PAHs and acidic pesticides	Aquatic samples (drinking water); and biological materials	Before SPME can be used with solid matrices, homogenization with a hydroalcoholic solvent and further filtration or centrifugation are required

HLB), along or together with strong anion-exchanger resins to improve the extraction of most polar analytes.

Solid-phase microextraction (SPME) is a miniaturized variation of the SPE, based on the partitioning of the analytes between the sample matrix and the stationary phase, which is coated on a fused-silica fiber. SPME with CE has been applied in environmental analysis to determine PAHs in water, and pesticides in vegetables. Trapped analytes can be desorbed by an organic solvent or directly into the CE electrolyte stream, via an adapter.

Examples of basic studies of offline extraction and preconcentration of pesticide residues using other techniques, such as online dialysis, steam distillation, supercritical fluid extraction, pressurized liquid extraction, cloud point extraction, or liquid–liquid membranes, have been reported. The large amounts of matrix coextractives and the need for clean extracts in CE/ultraviolet (UV) analysis are the main reasons for their scarce application.

**On-column preconcentration procedures** The word ‘stacking’ defines any on-capillary mode of concentration or focusing analytes based on changes of electrophoretic velocity due to the electric field across concentration boundaries. Sample stacking can be performed in both hydrodynamic (e.g., gravity or pressure) and electrokinetic (e.g., voltages) injection modes. The sample solution is sandwiched between two portions of the CE separation buffer. When high

voltage is applied across the capillary, the analytes move quickly through the sample until they reach the buffer zone where they slow down because of the different compositions of the separation buffer. Neutral compounds, which are determined using MEKC, do not take part in a normal stacking procedure because they are not accelerated in the high electric field that is developed across the injection zone. The stacking technique has several variations including those designed for neutral compounds, as summarized in **Table 4**.

Among the strategies developed for neutral compounds, sweeping and stacking with reverse migration micelles, with and without the insertion of a plug of water before sample injection, are well established for different pesticide classes (triazine, benzimidazole, ura, and carbamate), providing detection limits of the order of  $2\text{--}46\ \mu\text{g l}^{-1}$ . Evidently, by the application of a stacking technique, the detection sensitivity of analytes can be greatly enhanced (**Figure 6**).

An on-column trace enrichment method for electrochromatography of dilute samples, similar to stacking methods, involves online preconcentration by frontal electrochromatography under conditions of strong solute binding to the stationary phase, followed by a step-gradient elution electrochromatography with a mobile phase of high eluting strength. The effectiveness of this on-column trace enrichment procedure is largely influenced by the affinity of the individual analytes for the stationary phase.

**Table 4** Preconcentration in CE for environmental analysis

<i>CE mode</i>	<i>Principle</i>	<i>Remarks</i>	<i>Enhancement (<math>\times</math> fold)</i>
<b>CE</b>			
Stacking	Ionic analytes are focused in a sharp sample band, at the interface, between a low conductivity matrix and a high conductivity separation buffer	Broadening of the stacked zones injection not longer than 30 s without loss of the separation efficiency	3–30
Stacking with matrix removal	The sample buffer is removed after stacking reversing the voltage polarity (EOF is directed toward the inlet expelling the excess of sample buffer). The polarity is reversed again before the analytes are also removed from the capillary by EOF	The capillary can be filled with an extremely large sample volume retaining high resolution	100–1000
Isotachoforesis	Sample zones between the BGE of higher (leading electrolyte) and lower (terminating electrolyte) electrophoretic mobilities	Application to the microchip format	100–10 000
<b>MEKC</b>			
Stacking and stacking with matrix removal	Addition of SDS to the injection solution causes neutral analytes to behave like anions because they become adsorbed on the anionic SDS micelles	The two methods gave similar stacking efficiencies up to an injection volume of 80 nl	85
Normal neutral analyte stacking	Neutral analytes in a low conductivity sample without surfactant. Micelles from the BGE reservoir race across the sample zone toward the capillary inlet incorporating analytes. Once the micelles reach the boundary between the sample zone and the BGE they are stacked into narrow bands	The enhancement in detection limits is poor	10
Reverse neutral analyte stacking	Neutral analytes in a low conductivity sample without surfactant. Stacking is performed by applying a negative voltage at the inlet. As the sample solution is backed out the capillary by the EOF, micelles from the inlet buffer reservoir migrate to the detector. The polarity is reversed and the separation performed in normal mode	Improvement in the stacking efficiency The reproducibility of the method is limited by the analyst's ability to determine when to switch the polarity	20
Stacking with reverse migration micelles (SRMM)	Preparing the sample in a solution of lower conductance than that of the BGE, and without the surfactant. The potential at the inlet is negative and the EOF pushes the sample plug out of the capillary. However, the high concentration of positive charges reduces the EOF, producing the micelles' net migration toward the detector	The advantage of SRMM is that the focusing process and the removal of the sample occur upon the application of voltage at negative polarity	50
Stacking using reverse migration micelles plug (SRW)	SRW is performed unlike the previous procedure, injecting a water plug prior to long hydrodynamic and water injection	The advantage is that it provides a second enhancement field zone	100
Sweeping	Samples are injected in a buffer solution with a similar conductivity as that of the BGE but without surfactant. Separation is performed in negative polarity and with EOF suppression. As the micelles migrate from the BGE reservoir toward the detector they sweep the neutral analytes along	The effectiveness of this sample concentration technique has been shown to be dependent on the analytes' affinity for the micelle	80–5000

**Figure 6** Detection sensitivity of analytes measured under two different separation conditions: (A) without sample stacking (2.5 s injection with an injection pressure of 0.4 psi; sample concentration  $1.0 \mu\text{g ml}^{-1}$ ); (B) with sweeping-stacking (30 s injection with an injection pressure of 1 psi; sample concentration,  $1.0 \mu\text{g ml}^{-1}$ . Separation buffer,  $40 \text{ mmol l}^{-1}$  TTAB in  $40 \text{ mmol l}^{-1}$  phosphate buffer at pH 6; capillary,  $70 \text{ cm} \times 50 \mu\text{m}$  ID; applied voltage,  $-20 \text{ kV}$ ; detection wavelength,  $22 \text{ nm}$ ; temperature,  $25^\circ\text{C}$ ; sample concentration,  $10 \mu\text{g ml}^{-1}$ , sample dissolved in a sample matrix containing 4% of acetonitrile solution. Peak identification: 1, simetryn; 2, ametryn; 3, prometryn; 4, terbutryn. (Reprinted with permission from Lin CE, Liu YC, Yang TY, Wang TZ, and Yang CC (2001) Online concentration of s-triazine herbicides in micellar electrokinetic chromatography using a cationic surfactant. *Journal of Chromatography A* 916: 239–245; © Elsevier.)

Another way of enhancing the sensitivity of CE in environmental analysis is by on-column SPE, using a capillary column with a plug of reverse-phase material or a material bounded to the inner wall of the capillary. These approaches seem very promising but, to our knowledge, no applications to the environmental analysis have been reported till date.

### Detection Systems

The detection system is the other cornerstone to improve the concentration limits of detection. Although CE is more easily interfaced with optical detection methods based on UV–visible absorption and laser induced fluorescence (LIF), a variety of detection systems are suitable for the identification and quantification of inorganic compounds, organic contaminants, and NOM in the environment. Table 5 lists the most common detectors used in CE environmental applications.

The majority of CE instruments commercially available today are equipped with UV–visible absorbance detectors because of their wide range of

applicability. The most popular is the photodiode array (DAD) because it displays the UV spectra of eluting compounds. In these detectors, the capillary itself serves as the cylindrical detection cell constraining them to operate within the minuscule dimensions of the capillary. Although UV detection is very mass sensitive, concentration limits of detection are substantially higher because of the small injection volume used.

Inorganic ions are mainly UV-transparent, and most CE applications utilize indirect UV detection to quantify them. The key to this approach is the displacement of a highly absorbing electrolyte co-ion by the sample ions. Direct UV of these compounds requires a derivatization step using suitable chromophores prior to separation.

Organic compounds absorb appreciably at wavelengths below  $250 \text{ nm}$ , but the problem with the UV detection is that many reagents and matrix-derived compounds absorb in the same spectral region. Figure 3B illustrates the presence of endogenous peaks in an electropherogram of a tomato sample. For this reason, CE–UV analysis is more popular in very clean environmental substrates such as water.

LIF detectors are more sensitive and selective than the UV–visible absorption ones, but only a few different laser sources ( $488 \text{ nm}$  Ar ion,  $442 \text{ nm}$  He–Cd, and  $324 \text{ nm}$  He–Ca) are available. Direct detection of native fluorescence compounds separated by CE has been demonstrated for some fluorescent dyes. Fluorescence detection of other inorganic and organic contaminants is also achieved by indirect methods – either direct fluorescence by the formation of complexes or derivatives, or by incorporating a fluorophore into the BGE.

Table 6 summarizes the variety of chromophores, fluorophores, and derivatizing agents used in the indirect format of UV and LIF detection.

Recently, electrochemical detection methods, namely, conductimetry, amperometry, and potentiometry, have also become accessible. All three variants of electrochemical detection are intrinsically simpler than the optical methods, and their success depends highly on the electrode materials and designs used. Conductivity detection relies on measurement of the differences between the conductivities of the analyte and the separation electrolyte; this provides a direct relationship between migration times and response factor, and makes this detector universal. On the contrary, amperometric detection is restricted to electroactive species and potentiometric detection is not possible for certain small ions with multiple charges. Conductimetric detection works better for inorganic compounds since the higher mobility of

**Table 5** Different detection modes for capillary electrophoresis in environmental analysis

<i>Detection mode</i>	<i>Analyte types</i>	<i>Detection limits (mol)</i>	<i>Advantages</i>	<i>Disadvantages</i>	<i>Solutions</i>
UV-Vis absorption	All analytes	$10^{-13}$ – $10^{-16}$	Universal; easily interfaced; and spectral information using DAD	Low sensitivity; and substances UV-transparent	Work at wavelengths less than 200 nm; wide-bore capillaries; bubble or z-shaped cells; sample preconcentration techniques; and indirect by BGE or complexation
Fluorescence	All analytes	$10^{-15}$ – $10^{-21}$	Easily interfaced; sensitive; and selective	Few laser sources commercially available; few substance naturally fluorescents	Indirect by BGE, complexation, or derivatization
Electrochemical conductivity	Ionic	$10^{-18}$ – $10^{-20}$	Universal; relatively inexpensive; and easy to adapt	Low sensitivity; requires special electronic and capillary modifications	Use low conductivity buffers
Potentiometry	Ionic	$10^{-13}$ – $10^{-15}$	Universal	Not suitable for small multicharged ions; requires special modifications	Adequate selection of the ionophore
Amperometry	Electroactive compounds	$10^{-18}$ – $10^{-20}$	Sensitive and selective	Restricted to electroactive analytes	Indirect by BGE, complexation, or derivatization
ES-MS	All analytes	$10^{-16}$ – $10^{-17}$	Sensitive, selective; and structural information	Restriction in buffer choice	Partial filling and anodically migrating micelles procedures
ICP-MS	Cations	$10^{-13}$ – $10^{-16}$	Selective and enable determination of different valences	Limited number of detectable elements	

the small ions directly affects the detection signal. However, impressive results have also been achieved with this technique for many organic contaminants with weakly acidic or basic character. Amperometric detection is an electroanalytical technique most used to determine organic contaminants and is also a valuable method for most transition metals and some electroactive anions (composite anions such as nitrogen- and sulfur-containing species). In contrast, alkali and alkali-earth metals are not accessible to amperometric detection. Potentiometric detection methods have been reported mainly for inorganic

species, as this is the usual domain of ion-selective electrodes, but, as has been recently shown, it can also be used for organic species. A disadvantage in the application to organic ions is the poor selectivity for most multicharge ions.

Presently, the coupling of CE to MS is already an attractive approach, which is generating a growing interest because it facilitates the analytes' identification, overcomes a large number of interfering substances, and improves detection sensitivity. Electrospray (ES) is the ionization technique most successfully combined with CE by means of the

**Table 6** Indirect methods for environmental analysis by UV–Vis absorbance and CE–LIF

<i>Reactives</i>	<i>Analytes</i>	<i>Remarks</i>
UV–Vis absorbing electrolytes Creatinine, imidazole, ephedrine, pyridine, copper sulfate, 4-aminopyridine, 4-methylbenzylamine, benzimidazole, <i>p</i> -toluidine, <i>N,N'</i> -dimethylamine, malachite green, <i>o</i> -aniline, 1-(4-pyridyl)pyridinium	All analytes	Most universal and can be applied to many non-UV absorbing analytes if a suitable buffer system is selected
UV absorbing complexes Cyanide	Inorganic cations	Involves the formation of metal–ligand complexes The resultant negatively charged complexes require an appropriate electrolyte and an EOF modifier
Fluorescence electrolytes Cerium <sup>3+</sup> , fluorescein, 2,5-dihydroxybenzoic acid, quinine sulfate	All analytes	Restriction in buffer choice
Fluorescence complexes 8-Hydroxyquinoline-5-sulfonic acid (HSQ)	Inorganics	Most applicable to inorganics
Precolumn fluorescent derivatization 5-Aminonaphthalene-1-sulfonic acid (ANSA) 7-Aminonaphthalene-1,3-disulfonic acid (ANDSA) 8-Aminonaphthalene-1,3,6-trisulfonic acid (ANTS) Fluorescein isothiocyanate (FITC) <sup>a</sup> 9-fluorenylmethyl chloroformate <sup>a</sup>	All the analytes	ANSA enhances the enantio-separation
On-capillary derivatization Quaternary ammonium surfactants (CTAB) catalyzing the thermal decomposition of <i>N</i> -methyl carbamates to liberate methylamine Separation buffer contains the derivatizing components <i>o</i> -phthalaldehyde/ 2-mercaptoethanol	<i>N</i> -methylcarbamates	<i>o</i> -Phthalaldehyde is the most popular fluorescence reactant An intact capillary can serve consecutively as chamber for separation, decomposition, derivatization, and detection

<sup>a</sup> The reagent itself is fluorescent and must be removed or well separated from derivatized peaks of interest.

sheath flow interfaces. It holds the most prominent position in the field of environmental analysis. Forthcoming developments in CE/MS will focus on ES ionization with triple quadrupoles, double focusing instruments, ion traps, and time-of-flight mass spectrometers.

However, the application of CE–ES–MS to various environmental problems is still limited by the use of nonvolatile buffer components and organic additives, such as surfactants and chiral compounds, for achieving a wide variety of CE separations. Anodically migrating micelles and partial-filling (PFMEKC) techniques have been proposed to overcome these problems. In the first approach, the micellar velocity is directly manipulated by the adjustment of the EOF against the electrophoretic velocity of the micelle by changing the solution pH in MEKC. The elimination of MEKC surfactant introduction into ES–MS is

achieved with an anodically migrating micelle, moving away from the ES interface.

The PFMEKC consists in filling the capillary first with the background buffer (without surfactant) and then with the micellar buffer. After the analytes reach the detector, and before the SDS molecules elute from the capillary, the separation is stopped.

The hyphenation of CE with element-selective inductively coupled-plasma mass spectrometry (ICP–MS) has been proven to be an ideal technique to make elemental speciation measurements and to characterize NOM. However, ensuring accuracy is still a challenge and many factors, which may potentially change the form of the analyte when establishing sample preparation and storage procedures, should be taken into account. The same precautions necessary for accurate CE and/or ICP–MS measurements must be considered.

Other new detection methods, including radioactivity, X-ray, or flame photometric detection in the P-selective mode, or the coupling of CE to biosensor detection have been studied for the determination of environmental contaminants showing certain promising features, including high sensitivity and good selectivity, but these approaches have not received acceptance since they are not easily available yet.

## Introduction

Capillary electrophoresis (CE) has become an established technique in chemical analysis, including many applications in food chemistry. CE is an automated technique that bridges the gap between high-performance liquid chromatography (HPLC) and traditional electrophoresis techniques, offering separation modes whose basis ranges from zone electrophoresis through to chromatography. The most common

modes of separation employed for food applications are capillary zone electrophoresis (CZE) and micellar electrokinetic chromatography (MEKC). These two modes are complementary not only to each other, but also to the separation modes of HPLC. CE importantly offers the ability to control selectivity through straightforward changes to the run buffer composition while usually requiring no changes to the capillary. This is a considerable advantage in terms of the development of new methods, both in time and cost savings.

CZE separates sample components based on differences in their electrophoretic mobility, which is determined by their charge-to-size ratio. CZE is therefore only applicable to the separation of charged

molecules. Neutral molecules are not resolved from one another and migrate through the capillary under the influence of the electroosmotic flow (EOF).

MEKC can be used to separate both charged and neutral molecules. In MEKC, a surfactant (e.g., sodium dodecyl sulfate, SDS) is added to the run buffer at a concentration in excess of its critical micelle concentration. The surfactant micelles that are formed act as a pseudostationary phase, enabling separation upon the basis of partitioning between the hydrophobic core of the micelles and the aqueous buffer. This partitioning mechanism acts to enable the resolution of neutral molecules, whose migration with respect to the EOF will be influenced by the degree of partition into the micellar phase. Charged sample components are separated on the basis of charge-to-size ratio, although migration times and order may be influenced additionally by the synergistic partitioning mechanism.

CE applications in the field of food chemistry are becoming increasingly widespread, especially in the wake of several key developments in instrument technology that have brought significant improvements in terms of sensitivity, reproducibility, and flexibility. CE is applicable to as extensive a range of food components as it is possible to analyze by HPLC, but has the benefit of greater resolving power leading to shorter analytical run times. This article presents an overview of the current applications of CE to food chemistry, which are grouped in terms of the various food component types. The aim has been to show the diversity in these applications rather than to present an exhaustive review; therefore, the Further Reading list includes review articles that will provide more in-depth coverage.

## Proteins

Food proteins are vital nutrients and possess functional properties that can be exploited to modify and stabilize processed food structure. Protein content is therefore a significant factor in determining the commercial value of major food commodities such as cereal grains and milk. As a result there is intense interest in the development of improved methods for food protein analysis and the separation mechanisms provided by CE have brought the technique to the forefront of recent developments. The majority of methods employ straightforward CZE and MEKC based methodology, but in some cases capillary gel electrophoresis (CGE) or SDS-CGE (available as commercial kits) are employed. These latter separation modes employ a gel-filled capillary that allows

separation based on a molecular sieving mechanism. The major applications of CE to food protein analysis are in commercially important areas including the determination of protein quality, product authenticity, and processing and storage effects.

### Milk Proteins

Milk proteins are the most-studied food proteins and consequently the application of CE to their analysis is widespread. Milk proteins can be separated using CE according to genetic polymorphism, which enables the application of CE methods to establish genetic origins of milks used to produce various dairy products. Proteins and peptides are also key markers for studying the development of biochemical and organoleptic properties during processing of dairy products, such as heat treatment and drying. Such procedures can lead to protein denaturation and undesirable Maillard reactions, which may affect nutritional and flavor properties. Furthermore, proteolysis is an integral feature of the production of many dairy products, primarily cheese, leading to the formation of biochemical breakdown products that can have important implications for product quality (e.g., flavor). CE is a valuable tool for the separation and characterization of proteins and peptides following technological or proteolytic treatments.

Milk proteins consist of casein and whey protein fractions. Caseins are the major protein in milk and are sub-grouped into  $\alpha$ -,  $\beta$ -, and  $\kappa$ -caseins. Caseins form micelles that constitute the colloidal phase of milk, and the formation of these aggregates during CE analysis is prevented by adding  $6 \text{ mol l}^{-1}$  urea to the sample and separation buffers. Using a hydrophilic coated capillary and a low pH buffer (pH 3.0) containing polymeric additives (e.g., methylhydroxyethylcellulose) enables the separation of  $\beta$ -casein into its genetic variants according to differences in the number of basic amino acid residues. The use of these conditions is primarily in order to avoid protein adsorption to the capillary walls, which can lead to peak shape distortion and poor resolution.

As mentioned earlier, proteins can be used as markers for establishing genetic origin, which is a major issue concerning dairy product quality. A prime example is the adulteration of caprine and ovine milk products with small amounts of bovine milk. This occurs because of the high market price of caprine and ovine milk and seasonal fluctuations in their production. CE offers a simple and rapid approach to the detection of adulteration because it is able to resolve milk proteins according to

genetic polymorphism. Figure 1 shows the analysis of the casein fraction of a milk mixture of one-third of each species from which it is possible using multivariate regression analysis to identify and quantify the presence of caseins from the three species.

Whey proteins, which are a group of globular proteins that include  $\beta$ -lactoglobulin and  $\alpha$ -lactalbumin ( $\alpha$ -La), are readily separated by a variety of CE approaches. The method used is normally dependent on the application, and whether resolution of whey proteins and caseins is required within a single analysis. The US Customs Service use CE as a rapid method (5 min run-time) for the analysis of  $\alpha$ -La in milk protein powders to aid the enforcement of import duties on milk protein concentrates, whose duty classification is partly defined by their content of  $\alpha$ -La.  $\alpha$ -La is present at low levels in milk (<5% of total protein) and is subject to degradation/denaturation during processing of milk powders. Its analysis by CZE is simple, using a borate run buffer (pH 8.0) for separation after extraction of the protein into an acetic acid medium.

**Figure 1** Electropherograms of the casein fraction of a mixture of one-third each of bovine, ovine, and caprine milk. Peak identification: 1, bovine  $\alpha_{S1}$ -casein; 2, ovine  $\alpha_{S1}$ -casein; 3, bovine  $\kappa$ -casein; 4, ovine  $\kappa$ -casein; 5, bovine  $\beta$ -casein A<sup>1</sup>; 6, caprine  $\kappa$ -casein; 7, bovine  $\beta$ -casein A<sup>2</sup>; 8, ovine  $\beta_2$ -casein and caprine  $\beta_2$ -casein; 9, ovine  $\beta_1$ -casein and caprine  $\beta_1$ -casein. Conditions: hydrophilic coated fused-silica capillary 50  $\mu$ m i.d.  $\times$  57 cm; separation buffer, 6 mol l<sup>-1</sup> urea, 0.32 mol l<sup>-1</sup> citric acid, 20 mmol l<sup>-1</sup> sodium citrate, pH 3.0, containing 0.5 g l<sup>-1</sup> methylhydroxyethyl-cellulose; applied voltage, 25 kV; injection, 15 s; temperature, 45°C. (Reprinted with permission from Molina E, Martin-Alvarez PJ, and Ramos M (1999) Analysis of cows', ewes' and goats' milk mixtures by capillary electrophoresis: Quantification by multivariate regression analysis. *International Dairy Journal* 9: 99–105; © Elsevier.)

## Meat Proteins

Muscle proteins are an important component of meat and can be classified according to solubility as sarcoplasmic (water soluble), myofibrillar (salt soluble), or stromal (insoluble) proteins. The application of CE to the analysis of meat proteins has been predominantly for separation of sarcoplasmic proteins in aqueous extracts from fish, bovine, and chicken muscle. The sarcoplasmic proteins that are present are mainly metabolic enzymes and therefore their separation profiles are useful for the purpose of species identification. Some reports also exist of the simultaneous separation of sarcoplasmic and myofibrillar meat proteins using SDS-CGE.

## Cereal Proteins

Cereal proteins play an important role in food functional properties and have been traditionally separated and characterized using slab-gel electrophoresis techniques. CE is emerging as a valuable new technique for the analysis of cereal proteins, particularly to bring improvements in resolution and speed of analysis. Methods based on CZE and SDS-CGE can be used for a variety of applications, including cultivar differentiation and purity screening.

## Amino Acids

Amino acids are important nutrients and can be used as indicators of protein composition. However, they can pose difficulties for analysis because the majority of amino acids do not possess a chromophore. For this reason the major focus for method development in CE is not to achieve separation, which is relatively straightforward, but to achieve sensitive and selective detection. Two routes are possible to meet this end, which are either amino acid derivatization followed by laser-induced fluorescence (LIF) or electrochemical detection, or detection of underivatized amino acids by conductivity or electrospray ionization mass spectrometry (ESI-MS). An advantage of ESI-MS is that it gives greater accuracy in the assignment of electropherogram peaks, which can be vital for complex sample matrices. Figure 2 shows an example of the application of ESI-MS to the detection of amino acids in soy sauce. In this example, free amino acids are analyzed simultaneously using a low acidic pH to confer positive charge on the analytes.

## Maillard Reaction Products

The Maillard reaction is of critical importance in food chemistry and is the origin of many colors and

**Figure 2** CE-ESI-MS selected ion electropherograms for amino acids in soy sauce. Experimental conditions: fused-silica capillary 50  $\mu\text{m}$  i.d.  $\times$  100 cm; electrolyte, 1  $\text{mol l}^{-1}$  formic acid; applied voltage, 30 kV; injection 3 s at 50 mbar; temperature, 20  $^{\circ}\text{C}$ ; sheath liquid, 10  $\mu\text{l min}^{-1}$  of 5  $\text{mol l}^{-1}$  ammonium acetate in 50% (v/v) methanol–water. flavors, including some that are undesirable. The Maillard reaction is the nonenzymic browning reaction of reducing sugars with amines and typically involves amino acids, proteins, and peptides. The chemistry underlying the Maillard reaction is complex and it is therefore a major challenge to effectively separate and characterize the complete range of its products. These products often have closely related chemical or biochemical structures, thus the resolving power of CE has been widely applied to tackle their separation. CE is attractive for these applications because of its simplicity and high resolving power combined with minimal requirements in terms of sample preparation.

## Vitamins

Vitamins are a structurally heterogeneous group of compounds that are essential in the diet for the

maintenance of healthy growth and development. Vitamins can be classified into two main groups: the water-soluble vitamins (B-group and C) and the fat-soluble vitamins (A, D, E, and K). Water-soluble vitamins are readily separated by CZE and MEKC methods, and several approaches have been developed for their determination in foods. There are fewer applications that have been developed for the determination of fat-soluble vitamins in foods. However, it should be noted that it is possible to separate mixtures of fat- and water-soluble vitamins using MEKC or by methods that employ microemulsion droplets as the pseudostationary phase. Separations of such mixtures have not been realized by other separation techniques.

### Vitamin A

Vitamin A is present in foods as retinol and retinyl esters (usually retinyl acetate or retinyl palmitate). Retinoids are often employed as food additives

because of their beneficial antioxidant effects. To resolve mixtures of retinoids, which are fat soluble, the use of MEKC methods is required. The choice of micellar phase is important, because common MEKC micellar phases such as SDS or the bile salts sodium cholate and sodium deoxycholate all exhibit a strong solubilization effect on retinoids. They are therefore unsuitable since poor resolution is obtained. However, by using a mixed micellar phase comprising sodium deoxycholate and polyoxyethylene(23) dodecanol (Brij 35) it is possible to achieve separation of, for example, retinol and the retinyl esters.

### Vitamin B<sub>1</sub>

Thiamine (vitamin B<sub>1</sub>) occurs in foods in free and bound forms, the free form predominates in cereals and plants, whereas the pyrophosphate ester is the main form in animal products. Acid hydrolysis is required to release thiamine from the food matrix. Enzymatic hydrolysis is then needed to convert phosphate esters to thiamine. Prior to CE analysis it is necessary to clean up samples by using ethanol to precipitate protein and by passing through an ion-exchange resin. Thiamine has been determined in meat and milk samples using MEKC with ultraviolet (UV) detection at 254 nm, obtaining comparable sensitivity to that achieved by HPLC using an ion-pair reversed-phase column with postcolumn derivatization and fluorescence detection.

### Vitamin B<sub>2</sub>

The analysis of riboflavin (vitamin B<sub>2</sub>) and related flavin cofactors (flavin adenine dinucleotide and flavin mononucleotides) can take advantage of their native fluorescence, which enables LIF detection to be used. LIF detection is extremely sensitive and imparts a high degree of selectivity for the determination of flavins from food samples. Taking advantage of this selectivity, riboflavin can be separated using a straightforward CZE approach with a basic running buffer (e.g., phosphate buffer at pH 9.8). This has been applied for analysis of riboflavin in wines, vegetables, wheat flour, and tomatoes.

### Vitamin C

The principal compound with vitamin C activity that is found naturally is L-ascorbic acid. L-Ascorbic acid is readily oxidized in solution to L-dehydroascorbic acid, which means that methods for the determination of total vitamin C content require quantification of both forms. Acids are normally used for extraction to protect vitamers from degradation and to precipitate

associated proteins. Depending on the complexity of the sample matrix, ascorbic acid is separated using either CZE or MEKC and detected by UV at 254 nm.

### Niacin

Niacin is found in foods as nicotinic acid and nicotinamide, which are the free forms, and as the co-enzymes nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate. Niacin is stable and can be extracted into acids or alkalis. Niacin has been determined by CE in a range of food matrices, such as meat, fish, fruit, and vegetables, and CE is generally found to be faster and more cost-effective in comparison to established HPLC methods.

## Carbohydrates

A major issue for the determination of carbohydrates is the lack of a chromophore suitable for UV detection. In addition, most of the carbohydrate sugars are neutral and therefore cannot be separated by CZE. Both issues can be addressed by the use of an alkaline borate sample and running buffer, since sugar-borate complexes are negatively charged and can be detected by UV at 195 nm. However, more sensitive detection can be achieved by derivatization of carbohydrates with a fluorescent label via reductive amination of the reducing end. **Figure 3** shows the separation of 9-aminopyrene-1,4,6-trisulfonic acid (APTS) labeled  $\iota$ -,  $\kappa$ -, and  $\lambda$ -carrageenans by a CZE method using LIF detection. Carrageenans are sulfated linear polysaccharides that are used as

**Figure 3** Separation of mixture of APTS labelled  $\iota$ -,  $\kappa$ -, and  $\lambda$ -carrageenans, each 0.06 mg ml<sup>-1</sup>. Experimental conditions: fused-silica capillary 50  $\mu$ m i.d.  $\times$  47 cm; electrolyte, 25 mol l<sup>-1</sup> ammonium acetate, pH 8.0; field strength,  $6.4 \times 10^4$  V m<sup>-1</sup>; temperature, 50°C. (Reproduced with permission from Mangin CM, Goodall DM, and Roberts MA (2001) Separation of  $\iota$ -,  $\kappa$ - and  $\lambda$ -carrageenans by capillary electrophoresis. *Electrophoresis* 22: 1460–1467; © Wiley-VCH.)

gelling agents ( $\iota$ - and  $\kappa$ -carrageenans) or thickeners ( $\lambda$ -carrageenan) in food systems. The quantitative separation of carrageenan subtypes is possible by anion exchange or gas chromatography, but requires hydrolysis or methanolysis prior to analysis, which could lead to loss of molecular information contained in the intact structure. The analysis by CE is extremely rapid and uses an electrolyte system that would be compatible for use with ESI-MS detection.

## Food Additives

Food additives can be any substance added to a food to perform a particular function. The term is most commonly applied to preservatives, colors, and flavorings. Many food additives are synthetic molecules and therefore legislative requirements are in place to control their use.

### Preservatives

Several simple and rapid methods have been reported for the analysis of preservatives, which are additives used to prevent biological degradation of foods. Common preservatives include benzoic acid, sorbic acid, sulfite, and *p*-hydroxybenzoic acid esters. The resolving power of CZE allows the facile separation of complex mixtures of preservatives whose separation by HPLC is less straightforward. For HPLC, the wide variation in polarity of the acid preservatives in comparison to the esters makes simultaneous determination difficult without the use of ion-pairing reagents. However, in CZE the charge-to-size ratio of the analytes is sufficient even to separate the methyl, ethyl, propyl, and butyl esters of *p*-hydroxybenzoic acid, which all have similar  $pK_a$  values but different molecular weights.

Anionic preservatives, such as sulfite (as sulfate), nitrite, and nitrate can be determined by reversing the polarity of the applied voltage and employing a cationic polymer capillary coating (e.g., polyethyleneimine) or a cationic surfactant buffer additive (e.g., hexadecyltrimethylammonium bromide, CTAB) to reverse the direction of EOF. This strategy, also commonly employed for the analysis of inorganic ions, allows faster separation since the anions migrate in the same direction as the EOF (anions conventionally migrate in the opposite direction to the EOF). Sulfate does not absorb in the UV region, so indirect detection is used with chromate as the absorbing ion. Advantages of CE over classical colorimetry and titrimetry methods include shorter analysis time, automation, and lower sample consumption.

### Antioxidants

Antioxidants occur naturally in many foods, but they are also important additives in fat-rich foods in order to prevent rancidity. Natural and synthetic antioxidants are commonly polyphenols, although some other natural antioxidants include ascorbic acid and tocopherols. Synthetic polyphenolic antioxidants are commonly separated in CZE or MEKC modes using an alkaline borate buffer. CE methodologies for the quantitative determination of natural polyphenolic antioxidants include the use of electrochemical detection, microemulsion electrokinetic chromatography (MEEKC) and nonaqueous CE (NACE). Electrochemical detection has been advocated for its high sensitivity and selectivity for electroactive analytes such as phenolic compounds. Indeed, the selectivity of electrochemical detection may be a useful approach to the determination of phenolic compounds in complex matrices, since it would minimize the extent of sample cleanup required. MEEKC is an interesting alternative to MEKC methods for phenolic compounds since it gives different selectivity, which can be valuable to separate structurally similar compounds such as the green tea catechins. The MEEKC mode of separation for neutral compounds is based on analytes partitioning between mobile charged oil droplets and an aqueous buffer phase. The microemulsion droplets are normally stabilized by the addition of a surfactant. NACE similarly allows improved selectivity and separation efficiency over aqueous-based CE methods for the separation of theaflavins.

### Food Colors

The majority of synthetic food colors are ideal candidates for separation by CE. This is because they commonly contain sulfonic acid or carboxylic acid functional groups that form negatively charged colored ions at alkaline pH. CE has also been applied to the analysis of natural colors such as caramels, which occur as four distinct classes according to the reactants used during sugar caramelization. CE analysis can be used to identify and quantitate the class of caramel present in a sample.

### Artificial Sweeteners

Sweeteners such as aspartame, saccharin, and acesulfame-K are added as sugar substitutes to reduced-calorie food and beverage products. All three of these commonly used sweeteners can be resolved in samples from reduced-calorie products using a mixed phosphate/borate buffer system at alkaline pH and including sodium deoxycholate as a micellar phase.

### Simultaneous Determination of Additive Mixtures

Some of the most elegant examples of the resolving power of CE have been applications for the separation of mixtures of food additives. There is a real need for such methods since mixtures of additives are often present in foods and beverages. This especially evident in reduced-calorie soft drinks, which are usually colored and include artificial preservatives to counter the loss of sugar as a natural preservative. **Figure 4** shows an example of a simple MEKC method that is able to resolve 13 components in a mixture of preservatives, sweeteners, and colors within a runtime of just 14 min. The use of MEKC is necessary to resolve benzoic acid and saccharin, which are not baseline resolved under similar CZE conditions. The mixture can be separated using CZE with a longer capillary, but this leads to long analysis times of the order of 30 min.

### Organic Acids

CE is widely accepted as a rapid and cheap approach for the determination of organic acids, which occur naturally in many foods and beverages, including beer, dairy products, and tomatoes. Organic acids are important contributors to the organoleptic properties of these and other foods. The rapid analysis of organic acids can be performed by CZE using reversed polarity and buffer additives such as CTAB or hexadimethrine bromide to reverse the EOF direction. This approach has been used for the analysis of tartaric

acid, which is an important by-product that is produced in large quantities during wine production and cannot be rejected into the environment. Wineries precipitate tartaric acid using calcium hydroxide to produce a solid residue containing calcium tartrate that can be later purified to recover tartaric acid. The analytical methodologies used to determine the tartaric acid concentration in these solid wine residues are often long and tedious and have poor reproducibility. However, CE can be used to analyze for tartaric acid very rapidly (2 min runtime) and reproducibly, giving a viable improvement to existing methodologies.

Organic acids are also added to products fraudulently in order to mask poor quality or to disguise origin. CZE has been validated for measuring citric, isocitric, malic, and tartaric acids as authenticity markers in orange juices. These acids can be separated after simple sample preparation involving only dilution and filtration. This approach is applicable to authenticity determination based on the unique organic acid profiles of different fruit juices. In beer, organic hop acids, specifically iso- $\alpha$ -acids and their reduced derivatives, are sources of bitter flavor and can be readily separated by MEKC to generate characteristic quality profiles.

A recent development for the analysis of organic acids has been the development of a novel device based on the principles of CZE that enables the fast detection of anionic components, including organic acids and inorganic ions, in sugar and wine samples. The device uses a shortened fused silica capillary to

**Figure 4** Separation of a standard sample containing 13 food additives. Peak identification: 1, caffeine; 2, aspartame; 3, sorbic acid; 4, benzoic acid; 5, saccharin; 6, green S; 7, acesulfame K; 8, sunset yellow FCF; 9, quinoline yellow; 10, brilliant blue FCF; 11, carmoisine; 12, ponceau 4R; 13, black PN. Conditions: fused-silica capillary 50  $\mu\text{m}$  i.d.  $\times$  48.5 cm with  $\times$  3 extended path length detection cell; separation buffer, 20  $\text{mmol l}^{-1}$  carbonate, pH 9.5, containing 65  $\text{mmol l}^{-1}$  SDS; applied voltage, 20 kV; temperature, 25  $^{\circ}\text{C}$ .

rapidly analyze samples in a runtime of <1 min with acceptable sensitivity that would suggest potential application as a near-real-time method for monitoring processing steps in sugar and wine production.

## Agricultural and Veterinary Residues

CE is viewed as a potentially important technique for the determination of pesticide residues in environmental and food matrices. This application needs simultaneous separation of multicomponent mixtures with low limit of detection. The application of CE for the determination of pesticide residues has been aided recently by the development of improved methods of sample enrichment and detection. These methods can overcome the sensitivity limitations presented by the small sample volumes that are normally analyzed. It is somewhat perverse that this limitation should also be one of the technique's advantages in terms of reagent consumption.

Various veterinary residues can be found in food, particularly antibacterial agents used as curative or prophylactic treatments in livestock. A concern with the presence of residual levels of these antibacterial drugs in foods is the increase in antimicrobial resistance. CE methods have been applied to the determination of drug residues in fish and chicken muscle. The quantitative analysis of oxolinic acid fish muscle can be achieved using CZE with a basic phosphate buffer (pH 9) after solid-phase extraction. Enrofloxacin and its metabolite ciprofloxacin are detectable in chicken muscle using LIF detection after separation by CZE in an acidic phosphate buffer (pH 2.2). Oxolinic acid and flumequine can be simultaneously determined in chicken by using a basic phosphate buffer (pH 8.02) and UV-visible diode array detection.

## Clinical Applications

**Z K Shihabi**, Wake Forest University, Winston-Salem, NC, USA

## Introduction

Capillary electrophoresis (CE) is a general, relatively new analytical technique for separation and quantification of a wide variety of molecules including

those of clinical interest utilizing narrow bore capillaries under high voltage. The flexibility of this technique stems from the ability to incorporate different additives easily in the separation buffer, which can interact with some of the analytes relative to others to alter their velocity in order to achieve the desired separation. Most of the clinical tests can be adapted to CE; however, in practice, some are better suited than others for analysis by this method. In general, large molecules, such as proteins and DNA and those that carry a charge are more suited to be analyzed by CE. Here, we discuss the most important applications.

## Nucleic Acids Analysis

The analysis of DNA by CE represents one of the best examples for application of this technique in clinical analysis where the low cost, the full automation, and the speed of analysis compared to the slab gels accelerated the implementation of this technique in sequencing the human genome. Polymerase chain reaction (PCR), the Genome project, viral detection, blood transfusion safety, and forensic identification are all pushing the widespread use of DNA analysis especially by CE further than most investigators have expected.

DNA is a complex linear biopolymer composed of long repeat of nucleotides, which carry the genetic information through their sequence in the form of different genes. It is present in a complementary base pair (bp) as a double-stranded helix. Because the DNA is present in very huge long strands, it needs to be cut first into smaller fragments by special enzymes (nucleases) before analysis. These fragments can be studied for the number of the bases (size), their sequences, or for the presence of mutations. Since these fragments are present in low concentration, below the detection of the instruments, the next step is amplification through PCR in the presence of a primer, enzyme, and nucleotides.

DNA molecules all carry essentially the same charge; thus, they cannot be separated by electrophoresis simply based on charge alone. However, the separation can be achieved much better based on size by molecular sieving. Gels with different pores or long polymers are added to the buffer to retard the migration of large fragments relative to the smaller ones. Traditionally, agarose gels are used to separate double-stranded DNA (dsDNA) fragments after digestion for mapping; while slab polyacrylamide gel (SPG) is used to separate single-stranded DNA (ssDNA) fragments for sequencing.

Initially, CE methods for DNA separations attempted to mimic those of the SPG by using the same gels. Capillaries of 20–80 cm length and 50–75  $\mu\text{m}$  diameter were filled with cross-linked polyacrylamide gels similar to those used in SPG. DNA samples are injected hydrodynamically or by electroinjection. Small DNA fragments migrate rapidly and emerge first while the larger ones migrate slowly and emerge later. Thus, the migration time is used to characterize these fragments. These gel-filled capillaries gave excellent separations. They were able to resolve a single base pair (1 bp) with good resolution up to 450 bp; however, they had several practical problems such as filling the capillary without introducing air bubbles, short lifetime, and high cost. However, later on, solutions of uncrossed polymer network have been introduced. They were easier to work with, less expensive, and gave better precision. These polymers no doubt have spurred the interest in employing CE for DNA analysis. The polymers include uncrossed polyacrylamide, many derivatives of cellulose, poly(vinylpyrrolidone), poly(ethylene oxide), and dextrans, with some of these being proprietary. These polymers are replaceable gels each time the capillary is filled. They separate fragments of DNA <100 bp to >2 kbp, and in some instances up to 12 kbp with resolution of  $\sim 10$  bp (Figure 1).

The dsDNA fragment separation in CE is accomplished as in the SPG based on molecular sieving after the PCR step of the DNA fragment, while the ssDNA requires also a denaturing substance such as urea or formamide. Some workers found cellulose polymers are more suited for large fragments while the linear polyacrylamide is more suited for the smaller fragments. However, the optimum concentration and the molecular weight are more important than the type of the polymer.

For DNA sequencing, enzymatic synthesis of the purified template is performed in the presence of deoxynucleotides, and specific labeled (fluorescent) dideoxynucleotides (analogues) that terminate the DNA strand at specific nucleotides. Thus, fragments with different lengths and with different labels complementary to the original are synthesized. These are resolved for size and with detection for the fluorescent terminal end by CE. A single base-pair separation is important with the ability to sequence large fragments of DNA on the order of  $\sim 1$  kbp. This can be accomplished in the CE by  $\sim 80$  min. The addition of intercalator dyes such as ethidium bromide or YO-PRO stiffens the structure of the DNA and thus improves the separation.

CE has been used extensively for fragment size analysis up to several kilobases (Figure 1) and for DNA sequencing. The dsDNAs after PCR amplification

**Figure 1** Separation of 11 DNA fragments in the untreated capillary by electrokinetic injection for 90 s at 5 kV (fragments: 1, 72; 2, 118; 3, 194; 4, 234; 5, 271; 6, 281; 7, 301; 8, 603; 9, 872; 10, 1078; 11, 1353 bp). (Reprinted with permission from (1999) *Journal of Chromatography A* 853: 349–354; © Elsevier.)

have been utilized to identify bacteria and viruses. The sequence is used often to monitor the changes in the DNA of the virus (e.g., HIV) to match the drug treatment with the genetic makeup of the infectious agent.

The detection of DNA can be performed by ultraviolet (UV) detection. However, this has poor sensitivity and subject to much interference. The addition of special dyes such as YO-PRO1, BODIPY, and thiazole orange to the separation buffer in CE enables the use of laser-induced fluorescence (LIF), which improves the detection by a factor of ~100 times. LIF eliminates the interferences from the nucleotides in the reaction mixture, which absorb light in the UV region. Also, because the sample is diluted, matrix effects become negligible. This enables introducing the sample by electrokinetic injection with stacking (concentration on the capillary) too.

Genetic diagnosis of an inherited disease or cancer often involves analysis for unknown point mutations, as well as known mutations in several genes. There is great demand for detecting mutation due to single nucleotide polymorphisms (SNPs) by fast and simple methods without the lengthy steps of sequencing. Among several techniques denaturing gradient gel electrophoresis, heteroduplex analysis (HA), and single-strand conformation polymorphism (SSCP) have been used frequently in slab gels and have been

applied later on to CE. SSCP is one of the most frequently used methods for detecting unknown mutations. In this method, the strand is amplified through PCR and denatured through heat and formamide. The separated strands adopt special folded structures determined by their nucleotide sequences. A single base alteration is detected by SSCP when the folding of the single strand changes (conformational) sufficiently to alter its electrophoretic mobility. Change between the amplified DNA of the wild type and mutation is detected by CE. The gel concentration and the presence of additives are important for the detection, with the temperature effect on mobility being a key element. A short-chain polyacrylamide is helpful in this technique.

HA for detecting SNP has also been applied to CE. In HA, the PCR-amplified DNA of allelic fragments are denatured and re-annealed to give a mixture of four duplexes, two homoduplexes and two heteroduplexes, in the heterozygote samples. Heteroduplexes have an aberrant, distorted structure with bubbles or bulges at the sites of mismatched bases, and generally move more slowly in the gel than homoduplexes. Thermal-profile SSCP is unique to CE. In this method, a temperature program is used to follow the conformational changes. All these methods have been applied to the detection of SNPs of many genes, for example, all *BRCA1* and *BRCA2*

mutations, P 53, and C 677T methylene tetrahydrofolate reductase mutation. CE has the advantage of speed, low cost, and full automation over SPG. Several machines have been designed specifically for DNA analysis. Some of these instruments use multicapillaries (8–300) to speed up the analysis.

### DNA Chip

In order to speed up further the analysis and conserve the expensive reagents, the chip, a small piece of glass, silica, or plastic, has been introduced for chemical analysis with two distinct types of chips: binding and separation. The binding chip contains on its surface certain molecules that recognize and bind specific analytes such as DNA or protein. The DNA binding chip (DNA microarray chip) contains on its surface hundreds of certain oligonucleotides that bind complementary genes and thus hundreds or even thousands of genes can be analyzed simultaneously on a very small surface. The separation chip is etched on its surface with multiple microgrooves (typically about 5–20  $\mu\text{m}$  deep and  $\sim 5\text{ cm}$  long) in place of the capillaries or columns to serve for the separation.

The main advantages of the chip include very rapid separation (in terms of seconds) while the reagent consumption is minimal, with no moving parts to wear. This is achieved because of the narrow and short dimensions of the etched grooves. In addition to that, many channels can be etched, so several reactions can be carried out simultaneously in the same chip. Several analytical steps can also be performed on the chip such as reagent movement, mixing, separation, and detection. These chips and the instrument to detect the reaction are commercially available now. Some of these chips are aimed for use at the point of care (physician's office, or hospital bed).

### Proteins, Peptides, Polypeptides, and Amino Acids

Proteins and peptides are composed of amino acids. They are zwitterions carrying both positive and negative charges. The peptides and polypeptides are similar to proteins in structure but smaller in size. While DNA carries the genetic information, proteins perform catalytic, hormonal, and structural functions. In many of the proteins of clinical interest, such as the urinary protein uromodulin, their functions are not well understood; nevertheless, they remain to be important and vital. Proteins are important for their function as well as for their diagnostic significance. CE is useful for quantitation, purity

check, isoforms, and microheterogeneity detection of proteins.

The interest in protein separation for clinical diagnosis by electrophoresis dates back to the work of Arne Tiselius (around 1937). Because proteins have different amino acid compositions with different isoelectric points they tend to behave differently in capillary zone electrophoresis (CZE). For example, basic proteins tend to bind to the capillary wall and give distorted peak shape. To improve their separation by CE, different additives, high salts, or coated capillaries are used to decrease the binding to the walls.

In CE, after the sample is injected and separated it is detected by monitoring the absorbance of the peptide bond at 214 nm. Thus, the advantages of CE over agarose gel (AG) electrophoresis for analysis of proteins are the speed, automation, small sample volume, and avoidance of staining–destaining steps. This led some companies to design instruments dedicated only to protein analysis by CE. Furthermore, other manufacturers designed special CE instruments to perform capillary isoelectric focusing (CIEF) with absorption imaging detectors in order to focus, concentrate, and separate better the different proteins. These instruments can detect protein microheterogeneity better than the common CZE instruments. Presented below are some clinical applications of proteins and peptides measurement by CE.

### Serum Proteins

Serum proteins comprise more than a few hundred different proteins. However, for clinical diagnosis, they are separated into 5–12 bands by AG electrophoresis, which is a time-consuming method. They are analyzed routinely on a daily basis in most large hospitals to detect several disorders such as renal failure, infections, and most importantly monoclonal gammopathies.

In CZE, serum proteins can be separated also into 5–12 zones using different buffers such as Tris, borate, and tricine, with a pH of 8–11. Serum protein separation can be completed by CE in  $\sim 2$ –10 min in contrast to 1–2 h for AG (Figure 2). The correlation coefficient between CE and AG for the separated bands is good. Transferrin isoforms, which are important as marker of alcoholism, have been separated by CZE. Some commercial instruments use multicapillaries of narrow diameter (25  $\mu\text{m}$ ) to increase the throughput of the analysis. The narrow capillaries produce better resolution than the wider capillaries with a shorter migration time.

Serum immunoglobulins are composed of heavy and light chains and classified based on their reaction

with specific antibodies into the classes of: IgG, IgA, IgM, IgD, and IgE. Multiple myeloma, Waldenström's disease, and light chain disease can cause increased levels of these proteins (paraproteins). These paraproteins are detected with immunofixation, a laborious procedure performed in gel electrophoresis. CZE has been adapted to perform the immunofixation method based on reacting serum proteins with specific antibodies bound to a solid matrix. The sample is assayed before and after binding. The difference between the two 'immunofixations' represents the specific type of the

monoclonal abnormal serum protein. This method has been shown to be reliable.

### Cryoglobulins

Cryoglobulins are special immunoglobulins that reversibly precipitate from serum at cold temperatures. Cryoglobulins can be classified as monoclonal globulins (type I), mix of polyclonal-monoclonal (type II), or mix of polyclonal-polyclonal (type III) immunoglobulins. Cryoglobulins can precipitate in different tissues of the body such as the kidney and the extremities. They are associated with several immune-type disorders, viral infection, glomerulonephritis, peripheral neuropathy, and diffuse vasculitis.

Cryoglobulins are detected by precipitating an aliquot of the serum at 4°C, centrifuging and dissolving the precipitate in a buffer followed by electrophoresis using the same conditions as those for serum proteins (**Figure 3**). Cryoglobulins are well suited for analysis by CE. The main advantages are the higher sensitivity, the use of small volumes of serum, speed, and improved quantification compared to the AG method.

### Urinary Proteins

Usually urine proteins are present at ~10–100 times lower concentrations as compared to serum. In

**Figure 2** Serum electrophoresis of a patient with a small monoclonal band: (top) CE; (bottom) agarose electrophoresis (I = internal standard; A = albumin;  $\alpha_1$  =  $\alpha_1$ -globulin;  $\alpha_2$  =  $\alpha_2$ -globulin; T = transferrin; C = complement; M = monoclonal band;  $\gamma$  =  $\gamma$ -globulins; X = marker). CE conditions: capillary 30 cm  $\times$  50  $\mu$ m (ID), 9 kV, detection at 214 nm. Separation buffer: 7 g boric acid, 7 g sodium carbonate, and 5 g of polyethylene glycol 8000 in 1000 ml water.

**Figure 3** Type II cryoglobulin of a patient by CE: top (C) is cryoprecipitate, and bottom (S) is serum (A = albumin, G = globulin, M = monoclonal peak). CE conditions as in **Figure 2**.

addition to that urine contains numerous interfering UV-absorbing compounds. This renders urinary proteins more difficult to measure by CE when compared to serum. The urine contains several proteins of clinical interest, especially Bence–Jones proteins. Some urine samples can be analyzed directly without any preparation. However, the majority require concentration before the analysis using membrane concentrators. The same buffers and conditions for serum proteins are basically used for analysis of urine protein.

### Cerebrospinal Fluid Proteins

The main clinical significance of cerebrospinal fluid (CSF) protein electrophoresis is for the detection of the oligoclonal bands, which are present in multiple sclerosis in the gamma region. Because proteins in CSF occur at much lower concentrations than in serum (100 times less), a 10–20-fold sample concentration is needed. CSF protein separation can be accomplished in less than 10 min with CE versus 2 h for AG with the ability to detect oligoclonal banding by this technique.

### Enzymes

Since enzymes are essentially proteins they can be measured in CE by direct UV absorbency or by their enzymatic activity. The enzyme, the substrate, or the

products can all be measured in CE. Catalytic activity is more suited for enzymes with low activity because the reaction product can be amplified easily several fold. On the other hand, enzymes, which are present in high concentration, can be measured directly by their light absorbency.

In CE, catalytic activity can be measured in several ways: (1) incubation in the capillary, (2) online, postcapillary reaction, and (3) incubation outside the capillary. If a long incubation step is needed then it is more convenient to perform the incubation outside the instrument. Proteolytic enzymes with low activity are well suited for analysis by CE in this manner. Several enzymes have been analyzed by CE such as chloramphenicol acetyl transferase, glutathione peroxidase, ornithine transcarbamylase, angiotension converting enzyme, and Cathepsin D (Figure 4).

The advantages of CE for analysis of enzymes are the use of small volumes, versatility, and ability to avoid the extra steps of indicator reactions. In practice, kinetic spectrophotometric methods remain to be most widely used for routine work while CE is reserved for difficult and specialized tests.

### Hemoglobin Variants, Hemoglobin A1c, and Globin Chains

Hemoglobin (Hb) carries the oxygen. Its level is used clinically as indicator of the presence of different

**Figure 4** Enzymatic activity of breast tumor homogenate activity ( $106 \text{ pmol mg}^{-1} \text{ protein}$ ) at different periods of incubation: A=0 min; B=10 min; C=20 min; and D= at 20 min in the presence of pepstatin (P=split peptide, I=iothalamic acid (internal standard); and T=pepstatin). (Reprinted with permission from (1996) *Journal of Chromatography B* 683: 125; © Elsevier.)

types of anemia. Hb is present as two  $\alpha$ -chains and two  $\beta$ -chains. The  $\beta$ -chain is more susceptible for amino acid substitution (mutations), which results in specific variants that occur often in special populations. Some of these variants are harmless; however, others are associated with severe anemia, decreased capacity to carry oxygen, and altered red blood cell shape. The most encountered variants of Hb are A, F, S, and C. Because of the small charge difference of the isoelectric point (pI), Hb variants do not separate well by CZE. For good separation of Hb variants by CZE, a high buffer concentration, a narrow capillary (20–30  $\mu\text{m}$  ID), minimum volume of sample, and low voltages are required. Tris, tricine, and arginine buffers at pH 8–8.4 give a good separation. The separation by CZE resembles very closely that of the alkaline separation by AG.

Although CE instruments are not well designed for CIEF, many variants can be separated better by this technique. In addition to the common variants, HBA<sub>1c</sub> (a good measure for long-term hyperglycemia in diabetes), G Philadelphia, A2, and Bart's can all be separated by CIEF. The separation by CIEF compares well to high-performance liquid chromatography (HPLC) and to gel isoelectric focusing. The variants have also been analyzed by both CE and CIEF equipped with special absorption imaging detectors. These types of detection devices eliminate the extra steps needed to move the peaks, after the focusing step, to the detector and can simultaneously detect several capillaries with better precision and faster results than CE instruments. The globin chains, which are useful for investigating the thalassemias, have been analyzed by CZE in phosphate buffer either at pH 11.8, or at pH 2.5–4.5 after acetone precipitation. Furthermore, the tryptic digests of the globin chains were analyzed by CZE.

### Peptides and Polypeptides

Peptides can arise from the digestion of purified proteins. In this case, they are present in high concentrations and can be analyzed using the same or similar conditions for proteins. There is a great interest in peptide analysis as means to identify those proteins coded by the different genes discovered recently. After hydrolysis of the protein the different peptides are separated and analyzed by mass spectra. Online protein digestion using the bacterial peptidase followed by fluorescence detection, or mass spectra coupled to CE, has been described. On the other hand, peptides can present naturally in different biological fluids such as in serum or spinal fluid. In this case, they usually are present in low concentration among several interfering substances. Thus,

the analysis becomes more difficult. For example, glutathione in blood has been analyzed by CE. Peptide analysis by CE can be used for quality control or purity check in the pharmaceutical industry. In this respect, CE is well suited for this purpose. For example, endorphins, insulin peptides, aprotinin, and substance P all have been analyzed by CE (Figure 5).

### Amino Acids

Amino acid analysis is used in three distinct areas:

1. Detection of certain inborn errors of metabolism, such as phenylketonuria or maple syrup urine disease, where analysis of a single or very few amino acids present in high concentration is sufficient. This task is a relatively simple one. Several amino acids have been determined for this purpose by CE such as tyrosine, proline, and phenylalanine.
2. Protein hydrolysate, and amino acid mixtures: This analysis is important in determination of the structure of protein or its nutritional value. Here, the analysis of ~20 amino acids is sufficient. This type of analysis is relatively more difficult than that for a single amino acid. Most of the CE work is aimed at this type of analysis.
3. Free amino acids in physiological fluids, where the separation is much more difficult because of the need to separate also the other interfering natural substances (such as small peptides) in addition to the amino acids.

Analysis of amino acids poses several problems. The majority of amino acids lack a strong chromophore. Thus, they need extra steps to be derivatized pre- or postseparation. Since most of the amino acids are very similar in structure they are difficult to separate. Physiological fluids like serum contain many interfering compounds such as peptides and the uncommon amino acids.

Many workers have attempted analysis of amino acids by CE using different pre- and postreactions to enhance their detection. Both free CZE and micellar electrokinetic capillary chromatography (MEKC) have been used with different degrees of success similar to that of amino acids detection by HPLC. The separation of amino acids is better achieved in coated capillaries and also better with MEKC. Derivatization, especially with fluorescent agents, offers much better sensitivity. Several additive agents such as urea, cyclodextrin, and tetrabutyl ammonium salts improve the separation of amino acids. The analysis of amino acids from biological fluids by CE without interference and with good reproducibility remains a challenge. A dedicated CE instrument for amino

**Figure 5** Separation and stacking of some natural peptides (A = angiotensin, I = insulin B chain, C = impurity in the insulin B chain, and E = Leu-enkephalin). Top at 1.5% loading of the capillary and bottom at 30%. (Reprinted with permission from (1996) *Journal of Chromatography A* 744: 231; © Elsevier.)

acids separation is an attractive idea and might someday be commercially available.

## Drug Analysis

Drugs are analyzed clinically for several purposes: metabolism, pharmaceutical, forensic, and therapeutic drug monitoring (TDM). The majority of drugs present in serum can be analyzed successfully by any of several techniques including immunoassay, CE, gas chromatography (GC), and HPLC. Because of the ease, convenience, and automation, immunoassays remain to be the favorite choice in routine laboratories. However, new drugs usually do not have commercial immunoassays available and the real choice for these drugs is between HPLC and CE. These two methods are complementary to each other. However, CE, when compared to HPLC for TDM, is faster and easier with better resolution especially for the polar compounds with less operating cost. The capillary is less expensive than the HPLC column and

can tolerate extreme pH and direct protein injection. The use of large volumes of expensive organic solvents in HPLC is not needed in CE. As the environmental protection and safety rules are getting tighter, with regard to organic solvents disposal, the merits of CE become more evident. Methods development for drugs in general is faster by CE and the sample size is very small in CE.

Most of the analysis for drugs by CE utilizes either CZE in free solutions or MEKC in the presence of micelles. The two methods are complementary to each other. Drugs that are not sufficiently water soluble can be analyzed by nonaqueous CE (NACE). The separation in this method occurs in organic solvents in place of aqueous buffers. NACE offers several advantages for the analysis of such drugs, e.g., better solubility, different selectivity, and the ability to use higher voltages.

Since a main problem in CE is the poor detection limit, several strategies to concentrate the drugs from the biological samples by stacking (sample

concentration on the capillary) and by extraction are employed. Many new extraction methods are emerging as more suitable for CE, such as solid-phase microextraction compared to the traditional method of liquid-liquid extraction.

Several clever ideas have been described to obtain basic information on drugs utilizing CE; e.g., fast  $pK_a$  determination or drug binding to proteins and cell membranes. Commercial CE-mass spectrometry instruments are now available for drug metabolism and for drug confirmation. Most of the drugs have been determined by CE such as pentobarbital, theophylline, iohexol, keppra, and lamotrigine. As an example, analysis of the drug fenofibric acid in serum by CE with stacking is shown in **Figure 6**. The sharp peaks (high plate number) and fast analysis is evident in this figure.

### Chiral Separations

About 40% of the drugs contain at least one chiral center. Isomers have very close chemical structures; however, in many cases they exhibit different biological effects, bind to proteins, or are metabolized differently. Thus, chiral separation is very important. The principles of this technique in CE depend on the addition to the buffer an additive compound with a special cavity such as cyclodextrins, heparin, or certain antibiotics, which

selectively interact with the migration of one isomer. Chiral selectivity results from inclusion of a hydrophobic portion of the solute in the cavity and also from hydrogen bonding to the chiral hydroxyl groups. Because the amount used in CE is very small, the expensive chiral additives are usually added to the buffer and the separation is performed by MEKC. CE and capillary electrochromatography (CEC) are becoming more utilized for this purpose. CEC utilizes columns similar to those of HPLC but the buffer movement performed is driven by voltage rather than by a high-pressure pump. The advantage of CEC over HPLC is the higher plate number. In CEC, the chiral separations can be performed by columns similar to those for HPLC or by adding the chiral selector directly to the mobile phase. Rapid methods for chiral separation based on using the short end of the capillary with highly sulfated cyclodextrins have been described. These stereoselective methods are being applied to the analysis of drugs not only in tablets but also to those in serum samples.

### Drug Screening

Drug screening for forensic and emergency room testing is performed in many labs mainly by immunoassays. Unfortunately, the migration time in CE is not reproducible enough for identification of the numerous

**Figure 6** Analysis of fenofibric acid (F,  $42 \text{ mg l}^{-1}$ ) in serum by CE, with stacking. Iohexol (I) is added as internal standard. Conditions of analysis: capillary of  $25 \text{ cm} \times 50 \mu\text{m}$  (ID), voltage 7 kV, wavelength 280 nm, sample size 13% of the capillary volume. Separation buffer as in **Figure 2**.

drugs. On the other hand, the mobility data are much more reproducible and can be used for this purpose. CE has the potential of being a simple, economical, and powerful method of separation.

CE offers two powerful modes of separation for the forensic drugs, which can be complementary to each other, CZE and MEKC. Early work has shown the promise of CE for drug analysis. Drug screening by CE is a very enormous task, which requires large effort for building up a computerized database for all the controlled substances with their mobility and spectral data.

## Ion Analysis

Ions, organic and inorganic, are difficult to measure by most methods, especially when present at low concentrations. In HPLC, they require special expensive columns. CE is quite suited for analysis of these charged particles. Because of their relative charge to the small mass they tend to migrate rapidly giving fast separation with very high plate numbers and at low cost per test. Both cations and anions can be analyzed in the same run. The separation can be based on simple free solution CE or based on suitable chelating additive. Cations in general are measured in a low pH electrolyte containing a UV active species (imidazole or benzylamine), while the anions are measured after reversing the electroosmotic flow and also after adding a high-mobility UV active species.

Many of the inorganic and small organic ions in the biological fluids have clinical and diagnostic importance. Inorganic ions in the serum are important for maintaining the osmotic pressure and the pH of

the cells constant to prevent muscle, renal, and heart malfunctions. These are measured routinely in clinical labs and they represent a large volume of the pathology lab work. In practice, most of the common inorganic ions such as Na, K, Ca, can be measured more conveniently by ion-selective electrodes in the clinical labs. However, some of the uncommon ions such as nitrite and nitrate can be measured better with CE (Figure 7).

On the other hand, organic acids are more difficult to measure in the labs. Usually, these are measured by GC or HPLC. However, CE offers speed, precision, and specificity over other methods. Organic acids are important in inborn errors of metabolism, in infection, and different metabolic disorders. Many of these compounds have been measured by CE directly, or by indirect UV absorbency after addition of a UV absorbing compound such as benzoate, naphthalene sulfonate, imidazole, or benzylamine. For example, oxalate and citrate, which are important in stone formation, have been measured after urine dilution by both direct and indirect detections. Lactate, pyruvate, ascorbate, and oxalate were measured by CE in the CSF of patients in ~10 min. Methylmalonic acid, which is a sensitive measure of vitamin B<sub>12</sub> deficiency preceding any clinical symptoms or changes in the serum, has been determined in urine by CE after sample extraction and concentration.

## Miscellaneous Tests

There are numerous clinical tests that are less frequently analyzed by CE. Nevertheless, they remain to

**Figure 7** CE analysis of nitrite and nitrate in: (A) urine sample, (B) CSF sample. (Reprinted with permission from (1997) *Journal of Chromatography A* 781: 491; © Elsevier.)

be clinically important. Some examples are given below.

### Carbohydrates and Glycoproteins

Simple carbohydrates are important in diabetes and in inborn errors of metabolism. Carbohydrates bound to proteins (glycoproteins) are important for cell recognition, receptor interaction, and in immunity. Many of these compounds are also of pharmaceutical interest. The separations of transferrin isoforms, which are different in their sialic acid content, were among the first glycoproteins to be separated by CE. Other compounds such as ribonuclease, ovalbumin, tissue plasminogen, and human chorionic gonadotropin isoforms were separated later by CE. Borate buffers as well as the presence of different additives that affect the surface charge of the capillary (e.g., alkylammonium salts, diaminobutane, formic acid) are important for the separation.

Carbohydrates analysis by CE poses several problems. These compounds have poor UV absorbency. Their indirect detection depends on using buffers with high chromophoric ions such as sorbate, sulfosalicylic acid, tricarboxylbenzoic acid, and tryptophane. Simple sugars are not ionized unless the pH is above 12. They can be separated by CZE using buffers of NaOH or LiOH with added riboflavin for indirect UV detection. The use of small capillaries and efficient heat dissipation is necessary for a low baseline noise. Carbohydrates can also be derivatized with different fluorescent reagents or complexed with borate ions. As the chain length of the carbohydrate increases the analysis becomes more difficult.

### Lipids and Lipoproteins

Lipids and lipoproteins are important in atherosclerosis and coronary vascular disease. Some of the lipoproteins are atherogenic such as low-density lipoprotein (LDL) while others such as high-density lipoprotein (HDL) are protective. The different fractions of lipoproteins (e.g., LDL, HDL, Lp(a)) have been separated by MEKC. However, the separation by CE remains difficult and thus is not common.

### Immunoassays

In CE, analysis by immunoassays depends on the principles that the antigen and antibody migrate differently when they are bound compared to when they are free. One of these two compounds (mostly the antigen) is labeled with a fluorescent tag. The unknown sample is mixed with labeled antigen for competitive binding assay and the mixture is separated by CE. The label in the bound fraction (or

the ratio of bound to free) can be calculated and the unknown measured from a standard curve. These methods have been applied for the analysis of insulin, cortisol, and a few drugs. Unfortunately, this approach is not as simple or convenient as those commercially automated immunoassay instruments dedicated for this purpose.

### Single Cell Analysis

In many instances, such as in cancer, it is important to analyze a single or very few cells rather than homogenizing the whole tissue. Small capillaries of  $\sim 10\mu\text{m}$  in diameter have been used to study the level of some metabolites in single cells, e.g., catecholamines, 5-hydroxyindole acetic acid including the level of the enzyme lactate dehydrogenase. However, cell introduction into the capillary and lysis is not an easy task. Furthermore, this analysis requires the use of very sensitive detection.

### Stacking

Most of the clinical tests are below the direct detection of the CE instrument. In order to improve the detection limits, sample concentration either through extraction or on the capillary is utilized. Ionized compounds, in general, migrate more rapidly in dilute compared to concentrated buffers. In practice, stacking is a very simple technique to achieve. It depends on injecting a large sample volume (5–30% of the capillary volume) and performing the electrophoresis step under discontinuous buffer conditions: different pH, different field strength, or different buffers in such a way that the two edges of the sample migrate at different rates leading to narrowing of the sample plug leading to sample concentration (Figure 5). This step is done often simultaneously with the separation step.

## Introduction

Carbohydrates abound in Nature and are implicated in every form of living activity including commercial manipulation. The underlying reason for their analysis in matrices or for assessment of purity is to establish their identity and functions, and to control and utilize responsibly the resources they supply. Methods of carbohydrate analysis span a century, many of the early colorimetric, titrimetric, and gravimetric methods remaining indispensable, but being continually adapted to rapid and highly sensitive, accurate, automated procedures. A major breakthrough came 50 years ago with the development of chromatography, and of electrophoresis, as tools

for the separation of components in mixtures and subsequent application of a wide range of spectroscopic and electrochemical methods of detection, and of molecular structure determination. Modern analytical trends lie in the direction of ultramicroassay, based upon flow-injection analysis with voltammetric/amperometric detection, the automation of high-performance liquid chromatography (HPLC) in its various forms using fluorimetry and light scattering, ion chromatography with pulsed amperometric detection, and the use of biosensors with immobilized enzymes built into specific electrodes. Classical methods of planar and column chromatography based on adsorption and partition have largely given way to rapid, high-performance methodology including high-performance thin-layer chromatography (HPTLC), and HPLC on robust columns of graphitized carbon, or of modified silica for reversed-phase and hydrophobic interaction, or hydrophilic interaction chromatography, ion-exchange resins, immobilized lectins, and gels or their silica counterparts for noninteractive, size-exclusion chromatography (SEC). Capillary electrophoresis (CE) in different forms, using a

variety of sensitive detection methods, has undergone equally dramatic advances. These and other techniques are described in the sections that follow.

Impinging on the nucleic acid field, the technology of genetic manipulation has developed dramatically, restriction endonucleases being employed on a vast scale to characterize genes and the enzymes they encode, with a view to modifying products, such as starch and other polysaccharide components from plants, that could exhibit better functional uses. The medical field is set to benefit likewise through the targeting at molecular level the sites of infection or aberrant behavior, nuclear magnetic resonance (NMR) and X-ray technology being adapted to locating carbohydrate and other types of molecule at the sites of interest. As organic compounds carbohydrates and their derivatives are routinely analyzed for elemental composition, spectroscopic properties (infrared (IR), ultraviolet (UV), NMR, mass spectrometry (MS), ORD, and circular dichroism (CD)), and molecular mass (distribution) according to standard protocols, as an essential means of establishing identity and purity. These data are required particularly in the course of synthetic work. Selected information is needed for labeling products for marketing. In recent decades, dramatic advances have resulted from the use of computerized instrumentation and data handling.

## Structures

Carbohydrates in general are classified as (1) monosaccharides, which are polyhydroxy aldehydes (aldoses) or ketones (ketoses) with a continuous linear skeleton of carbon atoms (usually five or six), and (2) di-, oligo-, and polysaccharides, which comprise two or many more monosaccharide units joined as O-glycosides. Carbohydrates may be bonded covalently to amino acid constituents of proteins (as glycoproteins), to lipid (as glycolipids of varying complexity), and to lignin, tannin, flavonoids, terpenoids, or steroids by covalent bonds or as ill-defined association complexes. In all carbohydrate structures hydrogen bonding plays a highly prominent role, mediated in many instances by water molecules. Microorganisms, plants, and higher animals contain carbohydrate in the form of metabolites of short life, or oligo- and polysaccharides for energy storage, and as structural (cell wall) material.

The most abundant carbohydrate is D-glucose, which occurs usually in glycosidically bound form, though it is metabolized as phosphate ester and is found as the free 'sugar' in honey, plant nectars, and fruit juices. The predominant storage carbohydrate in plants is starch, a complex mixture of linear

((1); amylose) and branched (2); amylopectin)  $\alpha$ -D-glucans of which (2) usually predominates. It should be noted that isolates of (1), except in unusual circumstances, are accompanied by some branched material; the biosynthesis of starch is a complicated but well-understood process during which the linear molecules are progressively changed under the action of branching and debranching enzymes to form granular (2). The animal counterpart is glycogen, which resembles (2). Cellulose (3), a  $\beta$ 1 $\rightarrow$ 4-linked glucan, contributes hugely to biomass. The nitrogen-containing sugar derivative N-acetyl-D-glucosamine (2-acetamido-2-deoxy-D-glucose), units of which are linked  $\beta$ 1 $\rightarrow$ 4 as in cellulose, constitutes chitin (4), the shell coating of myriads of insects and crustaceans (lobsters) and a component of fungi, and is a vital component of glycoconjugates. The amphoteric compound muramic acid (3-D-lactyl ether of D-glucosamine) is ubiquitous as the N-Ac derivative in bacterial cell walls.

Isomers of glucose in approximate order of natural abundance are the ketosugar D-fructose (5), which when combined with glucose forms common sugar (sucrose), and the stereoisomers of glucose D-galactose (6) and D-mannose (7). The monosaccharides (all  $C_6H_{12}O_6$ ) are accompanied in Nature by the C6-oxidized derivatives D-glucuronic (8), D-galacturonic (often as Me ester), and D-mannuronic acids. Five-carbon sugars L-arabinose (9; compare the stereochemistry of D-galactose) and D-xylose (10) (related to D-glucose) are abundant in plant tissues (pectins and hemicelluloses), while D-ribose (11) and 2-deoxy-D-ribose are constituents of RNA and DNA, respectively. The 6-deoxy sugars L-rhamnose (12; stereochemically related to L-mannose) and L-fucose (related to L-galactose) are components of pectins, xyloglucans, mucilages, and glycoconjugates; critically important in its biological activity is the mannose derivative *N*-acetylneuraminic acid, one of an extensive family of sialic acids (13). These examples by no means exhaust the variations in structure found naturally. Rare but important sugar derivatives have seven-carbon chains (14). Antibiotics and steroidal glycosides contain sugar units modified by several changes of functional group, and a key unit in all pectins is the chain-branched aceric acid (15). Well over a hundred modified sugars (including many Me ethers, and the ketoacid Kdo (16)) are known to be constituent units in bacterial polysaccharides.

Many polysaccharide types are highly complex in structure, containing perhaps six or seven different sugar units in the molecule. Each of these units may be linked in several ways. The number of combinations actually found is, however, remarkably small considering the many possibilities that exist for the linkage of any two sugar units to each other, though variations in fine structure (microheterogeneity) are the norm in plant products. The capsular polysaccharides of bacteria, however, contain repeating units consisting of several sugars in well-defined sequences. Any

experimental work aimed at determining the molecular structure of a polysaccharide commences with a decision, often difficult, as to when the isolation procedure has reached a stage at which the polysaccharide sample might be regarded as sufficiently homogeneous to warrant further examination. Modern spectroscopic methods sometimes permit structural features to be observed in unmodified natural specimens. MS affords an accurate measure of molecular weights in solid samples: polysaccharides in solution usually show complicated molecular weight distribution patterns (in the range  $10^4$ – $10^7$ ).

The type of analysis to be performed varies according to the nature of the carbohydrate sample. If a mixture of monosaccharides is presented, chromatographic and spectroscopic procedures of many types are available to identify and quantify the sugars. Optical rotation measurements are invaluable in defining the purity of carbohydrate specimens, and in analyzing the composition of mixtures if the identity of the components is known. Differentiation between D and L enantiomers is best achieved on a small scale by conversion of derivatized sugars to glycosides using a chiral reagent, as the diastereoisomers formed have different thermodynamic properties and hence chromatographic retention times and NMR spectra. Alternatively, the sugars might be chromatographed on a chiral stationary phase. Polysaccharides present analytical problems at different levels according to their complexity; if the molecular structure is known, quantification is usually straightforward. The determination of the modes of linkage and sequences of the constituent monosaccharide units in complex polysaccharides, however, is a lengthy procedure requiring the application of numerous chemical, enzymatic, and spectroscopic techniques. Identification of the conformation, degree of crystallinity, and organization of the polysaccharide in its biochemical and physiological environment, or in foodstuffs, represents a further extension of the analytical problem.

## Main Reactions and Methodology

### Carbohydrate Reactions

The key functional group in carbohydrates is the carbonyl ( $>C=O$ ) group, which in sugars is masked by internal addition of an OH group in the same molecule to form five- or six-membered hemiacetals (named furanoses and pyranoses, respectively). Diastereoisomeric forms of each sugar, known as anomers, designated  $\alpha$  and  $\beta$ , are formed upon cyclization; this with the family configuration, determined as D or L by the highest-numbered chiral carbon atom,

denotes a particular molecular form of the sugar. Thus, for common D-glucose there are four forms ( $\alpha$  and  $\beta$ , furanose and pyranose). In solution these molecules equilibrate through the intermediary aldehyde, and for thermodynamic reasons  $\beta$ -D-glucopyranose (17) predominates. This form adopts a chair conformation, in which all the substituent groups on ring carbons are equatorial. The exceptional stability of this fundamental structure is manifested in the linear molecule of cellulose, the most abundant of all carbohydrates, in which the regular repeating unit is the dimer (cf. (3)). In cellulose the chains of D-glucose units ( $\sim 500$ – $10\,000$  in number) are united by extensive hydrogen bonding, and approximately one-half of the isolated material shows crystallinity. Starch in the form of amylose (essentially a linear  $(1 \rightarrow 4)$ - $\alpha$ -D-glucan) and amylopectin (having branches at O-6) presents many subtle variations in molecular structure and morphology (seen increasingly in genetically modified materials), and has properties and functions vastly different from those of cellulose, to which it is second in natural abundance.

The inter-sugar linkage in all di-, oligo-, and polysaccharides is the glycosidic bond, which is stable in water except when the carbohydrate is heated under acidic conditions or incubated with specific, hydrolytic enzymes (hydrolases). Mechanisms of glycosidic fission differ from those of the spontaneous ring opening and closing of the hemiacetal (ring) forms of monosaccharides. Consequently, the chemistry of the potential aldehydic groups in sugars (glycoses) is markedly different from that of the acetal linkages present in glycosides (see below). Every combination of sugars in carbohydrates comprising two or more units is characterized by one reducing end, nonreducing end groups in proportion to the number ( $n$ ) of chains, a corresponding number ( $n-1$ ) of branch points, and, in the case of polysaccharides, large numbers of chain units (18); these categories are subtly different in their chemical and biological properties. Fructans are essentially linear polymers of  $\beta$ -D-fructose, linked  $(2 \rightarrow 1)$  and  $(2 \rightarrow 6)$ ; the former, inulins, are unique because none of the ring atoms save the anomeric C-2 are included in the glycosidic, polymeric chains. As their name implies, the ends of chain units in cyclodextrins are joined, forming cages that are of

great importance in analytical separations based on stereochemical differences, and in pharmaceutical practice.

The carbonyl group in most carbohydrates is therefore masked (1) by hemiacetal formation in free sugars and in reducing-end sugar units, or (2) additionally by glycoside formation. The practical difference between (1) and (2) is that in solution the carbonyl function of sugars reacts as aldehyde toward oxidation (to yield carboxylic acid), and as aldehyde or ketone toward reducing agents (yielding alditols) and nucleophiles (forming derivatives). Complicated rearrangements follow enolization of sugars in aqueous alkaline solutions, so that they are intrinsically unstable at a raised pH, and lactone formation usually results after oxidation to the carboxylic acid. Reduction stabilizes the sugar molecule in these respects, yielding from an aldose a single product, and is accordingly widely exploited in analytical procedures. Only after hydrolysis (solvolysis) are sugars, released from being bound as glycosides, able to react as hemiacetals/aldehydes. The glycosidic bond being stable toward hydrolysis under neutral and alkaline conditions, the anomeric C atom in glycosides, disaccharides, oligosaccharides, and polysaccharides is not readily oxidized or reduced and is inert toward nucleophiles.

The hydroxyl groups attached to most carbon atoms in sugars and glycosides behave as do those in polyols, undergoing normal processes of dehydration, etherification, esterification, displacement, oxidation, and, in pairs, complex formation. They act as nucleophiles, displacing suitably activated anomeric hydroxyls of other sugar molecules to form glycosidic bonds. Hydroxyl groups are polar and hydrophilic, and form hydrogen bonds. In the special case of the primary alcohol functionality, oxidation proceeds to the carboxyl level, yielding, for example, the important D-glucuronic acid (8) and its lactone (19); Scheme 1.

### Analytical Aspects

If not soluble in water, carbohydrates are difficult to disperse otherwise. Anhydrous dimethyl sulfoxide, formamide, 1-methylmorpholine-1-oxide, 1-methyl-2-pyrrolidinone, and other aprotic solvents can sometimes be used, and sonication may be employed

Scheme 1

at risk of causing depolymerization of macromolecules; this procedure is a favored one for homogenizing plant tissues or foodstuff preparations prior to analysis. Enzymes may be needed to release polysaccharide components from their association with other substances in cellular tissue in order to bring them into solution in water, or to sever the glycan bond to peptide in a glycoconjugate. In view of the universality of HPLC methods of analysis it is advantageous to extract not with ethanol–water but with acetonitrile–water mixtures, which can be injected directly into the analytical system.

Analytical examination of solid samples includes observing effects of heat (melting point measurement, differential thermal analysis, and scanning calorimetry), and solid-state spectroscopy (IR, NMR, MS, X-ray). Microscopic observations play a part in identifying raw starch and its gelatinization. Investigation of aqueous solutions involves the measurement of chirality (optical activity for the sodium D-line; or ORD), viscosity and gel strength for polymers, and  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectroscopic parameters; the power and applicability of NMR and MS in particular has made an enormous impact in recent years. Carbohydrate extracts are invariably submitted to one or more of a wide range of chromatographic separations, which provide a means of characterizing sugars (or oligosaccharides) and their chemical derivatives, and of establishing the degree of homogeneity or purity of all carbohydrates, including polysaccharides and glycoconjugates.

Carbohydrates char on being heated and melting points (except those of derivatives) are not always reliable. Qualitative identification is performed by applying the time-honored purple-ring Molisch test (mixing 1-naphthol in aqueous ethanol with carbohydrate in water, and pouring concentrated sulfuric acid cautiously down the side of the tube containing the mixture). The test, of which there are many variants, is highly sensitive. Other phenols (orcinol, *o*-cresol, resorcinol), aromatic amines (aniline, *p*-anisidine, and carbazole), or anthrone produce colorations that distinguish one class of sugar from another, and uronic acids from neutral aldoses and ketoses; a

strong mineral acid is used to cause dehydration of the sugar, and the resulting furfural derivative combines with a phenol or amine to generate the chromophore. The standard Smith assay quantifies the reaction of phenol and concentrated sulfuric acid with carbohydrates generally, the optical absorption at 490 nm being compared with that of suitable calibrants. Carbohydrates separated on planar chromatograms are revealed when sprayed with such reagents. Derivatization of carbohydrates takes many forms, rendering them volatile (for GC), or changing polarity and providing easily detectable functional groups (for HPLC).

Structural analysis of oligo- and polysaccharides is most frequently accomplished by the methylation and hydrolysis procedure, modified if need be by reductive cleavage. Hydroxyl groups are converted quantitatively to methyl ethers of component sugar units, from which, after release and analysis, modes of linkage are inferred. Paper chromatography and TLC are simple and valuable tools for the separation of mixtures of methylated sugars; the extent of methylation and the positions of O-methyl groups are deduced from the mobility and color response of these derivatives to reagents such as *p*-anisidine hydrochloride. Methylated pentoses, hexoses, deoxyhexoses, and uronic acids exhibit different ranges of color. GC coupled with MS of suitable derivatives (methyl glycosides, acetylated aldononitriles, and alditols) is, however, the standard quantitative analytical procedure. Difficulties arise when uronic acid or acetamido sugar units are present in the carbohydrate; the glycosidic bonds resist acid hydrolysis and judicious derivatization is required to produce volatile substances for GC–MS identification. The contrary applies to polysaccharides containing acid-labile units such as D-fructofuranose (in inulins) or 3,6-anhydrogalactose (in agars and carrageenans) where such devices as protection by reduction with borohydride must be employed. Methanolysis may be an alternative to acid hydrolysis, and reductive cleavage is useful, but it is in the field of glycoconjugate analysis that this procedure becomes obligatory. The solubility of the analyte may favor methanolysis, particularly in working with glycolipids; and where such sensitive units as the sialic acids or certain sugar components of bacterial cell walls are present, methanolysis is essential; trimethylsilyl ether derivatives are most suitable for subsequent GC analysis. Separations of the mixtures of monosaccharides released on hydrolysis, if liquid chromatography (LC) is employed, do not necessarily require precolumn derivatization. Enzymes are used for many purposes, e.g., to estimate D-glucose or D-galactose, to establish anomeric linkages, and to effect hydrolysis or other

chemical change. Periodate oxidation of carbohydrates and analysis of the products is a technique applied extensively, and reaction procedures (degradations catalyzed by base) have been designed to localize and identify sugar units in proximity to uronic acid residues. Of prime importance is the application of NMR techniques to define the environments of H and C atoms and other bioelements in sugars or even in mixtures; intact oligosaccharides of great complexity may now be characterized spectroscopically. MS is informative at all levels of molecular size; however, the dramatic advances made in X-ray crystallography have afforded the most precise information as to conformational detail, with respect to helical structures in linear polysaccharides for example.

Sucrose (20) is a bulk chemical of exceptional purity, easily extracted and refined using relatively few steps. Some other sugars are also obtainable in crystalline form, but are generally hygroscopic. Polysaccharides retain moisture (5–10%) when air dried, the exact percentage being difficult to determine by thermogravimetry using vacuum-oven heating (microwave technology is feasible), or by Karl Fischer titration, and apart from cotton cellulose, some starches, bacterial exopolysaccharides, and plant exudates, very few can be isolated in a pure state without extensive chemical and physical manipulations. Many polysaccharides even defy exact definition, amyloids, pectins, hemicelluloses, and dietary fiber among them.

Family (R = e.g.,  $\alpha$ -D-Galp) of  
sucrose (R = H) derivatives

(20)

## Occurrence

Carbohydrates occur in all forms of life, and survive in plant and animal tissues for varying periods thereafter. Cellulose and the hemicellulosic components of dead wood decompose eventually under the action of enzymes secreted by fungi, whereas soluble carbohydrates disappear rapidly from plants and animals following well-established metabolic pathways. Industrially important carbohydrates, available in

bulk, include cellulose and mixtures of substituted xylans and glucomannans, which occur associated with the polyphenolic substance lignin in hardwoods and softwoods. In addition to the major nutritive components of cereal grains and vegetables (starches,  $\beta$ -(1 $\rightarrow$ 3) (1 $\rightarrow$ 4)-D-glucans and galactomannans), soluble and insoluble dietary fibers (xylans, pectins, and xyloglucans) are recognized as fulfilling an essential role. Natural sweeteners (sucrose, glucose, and fructose) are obtained from cane or beet, or from hydrolyzed corn (glucose, maltose, and related oligosaccharides). In food processing a variety of polysaccharides are employed to produce thickening and gelling; many such are of bacterial origin (xanthan, gellan, and scleroglucan), others are extracted from seaweeds (agars, carrageenans, and alginates), and some are obtained as exudates from trees and shrubs (gum arabic, gum tragacanth).

## Uses: In Foods, Heavy Industry, Biology, and Medicine

### Foods

The dietetic requirement for carbohydrate in humans and animals is well documented and has been widely discussed. A prime consideration is the ingestion of carbohydrate as an energy source, which is a staple need for all, especially in time of famine, and required in particular by manual workers and sportsmen among humans, and for the purposes of fattening livestock and caring for pet animals. Starch and commercial sugar are by far the most abundant carbohydrates consumed by humans (cellulose by ruminants) but for health reasons polysaccharides, which are not easily metabolized (dietary fiber), assume vital roles. Taste, texture, and palatability (mouth feel) are prime considerations in the supply of acceptable and adequate foodstuffs, and a range of different types of polysaccharide (hydrocolloids) are recognized food additives. Cooking normally being required, there are attendant chemical changes in the composition and properties of carbohydrates, and in their interaction with proteins and other constituents (cf. the Maillard reaction). Restrictions upon the sale, marketing, and distribution for food use of specific carbohydrates are imposed by legislation in most countries, and stringent attention to detail is required in the labeling of products; for this purpose and for assessing the nutritional value of foodstuffs, the importance of analysis is self-evident. Spoiling and the effects of ageing need to be assessed and monitored, together with the presence of contaminants or adulterants; these may include colorants, toxic substances, or compounds that contribute

adversely to taste, and usually require application of a wide range of analytical techniques. Low-calorie sweeteners are in demand, some of which (sorbitol = D-glucitol; maltitol; chlorine-containing sucrose derivatives) are related to sugars; others are bitter. It is not surprising, therefore, that some 5000 different analytical procedures are applied within a single large company (Eurofins) engaged in food analysis; the entries on food analysis in *Chemical Abstracts* exceed  $10^5$  in number.

### Food Additives (Hydrocolloids)

Because many persons in developed countries consume low-calorie and low-fat foods and high-intensity sweeteners, the analysis of these products is of great importance in meeting the requirements of health regulations. Starches (foods in their own right) and starch-derived polysaccharides, maltodextrins, pectins, cereal  $\beta$ -D-glucans, modified celluloses, bacterial gums, seed and algal polysaccharides, plant gum exudates, inulins, and semisynthetic polyglucose may all be added to prepared foods in varying amounts, either singly or as mixtures. These polysaccharides

(hydrocolloids) cause thickening of solutions and stabilizing of emulsions, promote gelling and affect numerous related improvements in functionality. The quantities incorporated in food preparations may be very large or as low as fractions of 1%.

Starch hydrolysates (dextrins, syrups) are extensively used in the food industry, the degree of polymerization (DP) of these oligomers of D-glucose being an important analytical characteristic. The DP may be estimated by determining the reducing power relative to glucose, there being but one reducing end-group unit in each molecule; alternatively, SEC using gels or silica-based packings in columns and calibrating with substances of similar structure and known molecular weight may be used as a direct measure of molecular size and distribution.

Table 1 lists some of these food hydrocolloids, and their utilization, together with a general description of their respective molecular structures.

### Other Applications of Hydrocolloids

The industrial uses of these polysaccharides are by no means limited to foodstuffs, and although the

**Table 1** Molecular structures and uses of food hydrocolloids

Hydrocolloid	Application <sup>a</sup>	Structure
Starch	Bakery, cereals, soups, meats, desserts, etc.	Essentially linear, (1 → 4)- $\alpha$ -D-glucan (amylose) Ditto, branches at O-6 (amylopectin), average chain length 25
Modified starches	Meats, dairy, soups, confectionery, starch pastes	Starch phosphates, acetates, adipates
Maltodextrins	Dairy, desserts, beverages, preserves, bakery, confectionery	Linear, (1 → 4)- $\alpha$ -D-glucans, mol. wt. <4000
Microcrystalline cellulose	Sauces, dairy, desserts, bakery, meats	Linear, (1 → 4)- $\beta$ -D-glucan, fibers <1–15 $\mu$ m diameter
Cellulose derivatives	Dairy, bakery, meats, batters, sauces	Ditto, $-\text{OCH}_3$ , $-\text{OCH}_2\text{CHOHCH}_3$ , or $-\text{OCH}_2\text{CO}_2\text{H}$ at C-6
$\beta$ -D-Glucans	Cereal products, bakery	Linear, (1 → 3) (1 → 4)- $\beta$ -D-glucans
Synthetic polydextrose	Confectionery, beverages, soft foods (laxative)	Branched D-glucan, random linkages
Seed xyloglucans	Jams, confectionery	Linear, (1 → 4)- $\beta$ -D-glucan, $\alpha$ -D-Xyl at O6, $\beta$ -D-Gal at O2 of Xyl
Konjac mannan	Low-calorie processed foods	Linear, (1 → 4)- $\beta$ -D-glucan and $\beta$ -D-mannan; $-\text{OAc}$
Seed galactomannans	Dairy, bakery, sauces, pet foods	Linear, (1 → 4)- $\beta$ -D-mannan, $\alpha$ -D-Gal- at O-6
Inulins	Dairy, beverages, confectionery, bakery	Linear, (2 → 1)- $\beta$ -D-fructofuranan
Xanthan gum	Dairy, sauces, meats, bakery, beverages	Cellulosic chains, substituted by $\beta$ -D-GlcA, T and $\rightarrow$ 2-D-Manp; $-\text{OAc}$ , pyruvate
Gellan gum	Confectionery, dairy	Linear, $\beta$ -D-Glc (2), $\beta$ -D-GlcA, L-Rha; $-\text{OAc}$ , $-\text{O-L-glycerate}$
Pectins	Preserves, jellies, dairy, health foods	Linear and branched, partly Me-esterified and O-acetylated (1 → 4)- $\alpha$ -D-galacturonan, $\rightarrow$ 2-L-Rhap $\rightarrow$ ; D-Gal, L-Ara, etc.
Alginates	Bakery, sauces, beverages, dairy	Linear, (1 → 4)- $\beta$ -D-mannuronan and $\alpha$ -L-guluronan
Agars and carrageenans	Bakery, dairy, confectionery, meats, sauces	Sulfated, linear galactans, including 3,6-anhydrogalactose, etc.
Gum arabic	Confectionery, beverages, sauces	Highly branched, (1 → 3) and (1 → 6)- $\beta$ -D-galactan, substituted by L-Rhap, D-GlcA, L-Ara; some glycoprotein
Gum karaya	Bakery, confectionery, dairy, meats	Modified pectin, partially acetylated
Gum tragacanth	Bakery, confectionery, dairy, sauces	Modified, acidic arabinogalactan, and modified pectin

<sup>a</sup> Food hydrocolloids are often used in combinations, so that an analyte (e.g., a fat replacer) can be expected to contain two or more different polysaccharides.

stringent demands imposed on edible products are not necessarily applied, their characterization by standard analytical procedures is normally required. The usefulness of hydrocolloids is based largely on their high capacity to attract water, producing thickening and gelling of aqueous solutions. Other functions, such as emulsification, suspension, flocculation, binding, and film formation, find outlets in the textile, adhesive, paint, paper, and mining industries, and the manufacture of pharmaceuticals and agricultural chemicals, as well as in large numbers of other trade applications.

### Heavy Industry

Cellulose is a well-publicized renewable and biodegradable energy source, at present in abundant supply ( $>10^8$  tons per annum), but subject to enormous demands from the paper and textile industries, for building purposes, and for fuel. The bulk comes from forests, particularly gymnosperms, for which the operations of milling and grinding prior to lignin removal are less complicated, while the most refined form is derived from cotton. The insolubility and inertness of cellulose, which contribute to the rigidity of plant tissues, form the basis of its chemical analysis; organic solvent extraction of the test material is followed by chemical treatment for the removal of reactive adhering substances, and the residual  $\alpha$ -cellulose is estimated gravimetrically. Cellulose may be assayed without isolation in a similar manner by degradation and extraction of the more-easily hydrolyzed components of the cell wall. Cellulose derivatives (esters, ethers) employed in the manufacture of fibers or prepared foods are identified and analyzed on the basis of the percentages of substituent groups present. Carbohydrate polymers generally constitute an important group of substances requiring special analytical approaches, including pyrolysis and GC-MS.

The starch content of agricultural products and foods is sometimes reported by difference after determining moisture, ash, organic solubles (lipid), and protein. The depth of blue-black colorations formed on interaction with iodine/iodide gives a direct estimate of I, while a host of methods are available for isolating and characterizing the size (1–100  $\mu\text{m}$  diameter), shape, and properties of starch granules (organized, hydrogen-bonded structures containing bound water), which reflect the plant source. Not all starch is soluble even in hot water, and recourse may have to be made to acid hydrolysis and estimation of the glucose released, with appropriate account being taken of other glucans present in the test sample. Amylose and amylopectin (as well as intermediate)

fractions can be separated using methods based on the formation of complexes with 1-butanol or thymol, combined with SEC, or by lectin affinity-chromatography. Commercial test-kits for measuring amylose to amylopectin ratios are available. Analyses based on enzymatic hydrolysis are specific and highly informative as to the molecular structures of starch components. Genetically modified plant sources give rise to starches that vary considerably in amylopectin structure.

### Biology and Medicine

Glucose (dextrose), fructose (laevulose), sucrose, lactose, dextrans, starch, and gums form the bulk of the carbohydrates in pharmaceutical use. Of the particular analyses performed upon biological fluids, automated procedures for glucose based upon reducing power, or color reactions linked with the use of insolubilized enzymes, outnumber all others; nevertheless, the range of substances analyzed that are derived from natural sources is vast, embracing carbohydrate molecules small and large. Glycoconjugates, glycoproteins, and glycolipids particularly are of immense importance in all living systems, and present numerous unique analytical challenges. The clot-dissolving drug tissue plasminogen activator (t-PA), the primary regulator of red blood cell formation in mammals, erythropoietin, and the blood anticoagulant heparin are examples of glycoproteins that are used extensively in the medical field. Not the least important use of carbohydrates is their conversion on an immense scale to fermentation products, from ethanol to antibiotics.

## Overview of Methods of Analysis and Their Merits

### Colorimetric and Spectrometric Methods

While there are many general reagents (anthrone, triphenyltetrazolium chloride), it is fortunate that the various classes of sugars (pentoses, hexoses, amino sugars, deoxysugars, uronic acids) respond differently to color tests, as these are generally easy to carry out with the aid of standard chemical reagents and simple photometric apparatus, and are readily adapted to automation. Well over 50 combinations of reagents were in use for these purposes as much as a decade ago. Absorbance is measured and the concentration of carbohydrate determined after calibration using purified, known substances. The method is applicable to monosaccharides and their methyl ethers, and is usually based on heating with mineral acid in the presence of one of a great variety of amines, amino acids, aldehydes, phenols, and many

other classes of organic compound. A quantitative method based on the reduction of 3,5-dinitrosalicylic acid has long been established.

Infrared spectroscopy (IR, near-infrared (NIR), and Fourier transform infrared (FTIR)) is universally applied to the characterization of carbohydrates along with organic and inorganic substances generally, and modern statistical analysis of data (chemometrics) has enlarged its usefulness. At higher levels of sophistication are other, modern spectroscopic methods of analysis, predominant among which are many forms of NMR spectroscopy and MS, the latter being normally coupled with chromatographic separations, GC and HPLC predominating. It is possible by NMR procedures to identify and quantify the common sugars in fruit tissues and to define the microenvironments of polysaccharide components in biological samples. Laser-assisted fluorescence spectroscopy and voltammetry coupled with electrophoretic and enzymatic techniques have brought the limits of detection of carbohydrates to picomole levels. MS in all its forms is now of universal application in carbohydrate analysis. Where crystalline material is available, the ultimate probe of molecular structure is X-ray diffraction technology. Such an approach is indispensable in the characterization of biopolymers, starch for instance.

### Enzymatic Methods

Although in a sense enzymatic techniques are ancillary to the use of chemical, chromatographic, and spectroscopic methods of analysis, they are in fact indispensable for many diagnostic and other purposes. Thermolabile and generally costly, especially when suitably purified (and this may be very difficult), enzymes are also subject in their action to end-product inhibition. On the other hand, enzymes are used only in catalytic amounts, are adaptable to microassay, are often rapid and uniquely specific in their mode of action, and are applicable both on a massive scale, as in degradation of cellulose and fermentation of starch, and, when immobilized and coupled with co-factors, in the detection and assay of sugars at medium to very low levels. The development of biosensors using enzymes is expanding rapidly. Enzymatic methods are ideally suited to the analysis of biological fluids and chromatographic eluates. Without enzymes it would be impossible to solubilize cell walls in order to study their components; carbohydrases bring about the reduction in size of polysaccharides and permit their release from encrusting material, and proteolytic enzymes or lipases effect the removal of unwanted substances from the carbohydrate to be isolated and examined. This is

specifically the case in the examination of dietary fiber, largely carbohydrate, which by definition is not decomposed by digestive enzymes. The molecular study and assay of all polymeric carbohydrates is virtually dependent on the use of hydrolyases and lyases for their degradation in a rational manner, exo and endo (e.g., with  $\alpha$ - and  $\beta$ -amylases). The resultant mono- and oligosaccharides are then conveniently analyzed with the aid of specific oxidases and dehydrogenases. A plethora of restriction endonucleases isolated from microorganisms is available for controlled DNA fragmentation and subsequent genetic manipulation of plants, for example, with accompanying enzyme changes and modification of the polysaccharides, such as starch, xyloglucan, galactomannan, or pectin, that they produce.

### Chromatographic Procedures

The degree of purity of a sugar sample can be ascertained or the identification and assay of mixtures of sugars can normally be achieved by any one or a combination of chromatographic methods, of which GC of volatile derivatives or HPLC with electrochemical detection of the sugars or derivatives prepared in order to confer suitable spectroscopic properties, are comparable in their efficacy. Supercritical fluid chromatography (SFC) is also a flexible, rapid, and efficient technique comparable with HPLC but by no means as widely used.

For sugar mixtures, GC on packed or capillary columns of varying polarity, with temperature programming, is carried out on alditol or aldonoitrile acetates, trimethylsilylated methyl glycosides, acetylated or trimethylsilylated oximes, N- or O-trifluoroacetyl derivatives, or any other suitably volatile derivatives. Retention times in comparison with standard derivatives provide a sufficient identification in most cases, but for more precise work MS with selected ion monitoring of fragments from the separated derivatives is advisable. MS is an invaluable approach to positioning the methyl substituents in sugar methyl ethers formed on hydrolysis of permethylated oligo- and polysaccharides, for example.

HPLC methods are extremely sensitive toward sugars and sugar derivatives, an important advance over detection by means of refractive index measurement lying in the use of ion chromatography with pulsed amperometric detection at copper, platinum, or gold electrodes. Analytical processes may be fully automated using various postcolumn derivatization procedures as required.

SEC enables carbohydrates to be differentiated, broadly on the basis of an average molecular weight. Thus, degradation products of many types of polysaccharide,

**Scheme 2**

mixtures of reduced, complex oligosaccharides (Scheme 2) from glycoproteins, and asparagine-linked glycopeptides have been analyzed by SEC.

DEAE-Sephadex is a column packing with both ion-exchange and size-exclusion properties, and chiral stationary phases have widespread uses. Affinity (or biospecific interaction) chromatography finds wide application in the purification of carbohydrates and glycoproteins. The technique of hydrophobic-interaction chromatography has been applied successfully to lignin-carbohydrate complexes and glycoproteins, the noncarbohydrate moieties being responsible for binding to hydrophobic groups in the column packings. Glycosaminoglycuronans (GAGs) have also been chromatographed on hydrophobic media. Ion-pair chromatography on reversed-phase columns is a process whereby such anionic carbohydrates as sugar phosphates, pectic oligomers, and fragments from hyaluronic acid, paired with the tetrabutylammonium ion, have been fractionated using aqueous eluents.

Modern methods employ CE with electrochemical detectors.

### Methods Used in Di- and Oligosaccharide Analysis

Sucrose and lactose occur naturally and are marketed on a huge scale, so that numerous standard procedures of analysis exist. Being furanosidic, sucrose requires special care in its extraction and handling, contact with aqueous acid to be avoided, and precautions taken against fermentation. Standard tables for specific gravity, refractive index, and specific rotation measurements (saccharimetry) have long been used, but modern techniques are based upon acid- or enzyme-catalyzed hydrolysis and assay of the reducing, glucose-fructose mixture ('invert sugar') produced. For this purpose, cuprimetric methods (Somogyi-Nelson; use of Munson-Walker tables) are well established and suitable for routine analyses. There are also biochemical techniques employing phosphorylases in coupled reactions that do not require prior hydrolysis. These approaches, to which numerous others including the use of IR reflectance and elaborate biosensors might be added for the analysis of

sucrose and related oligosaccharides, are general for di- and oligosaccharides, most of which are obtained in practice by cleavage of polysaccharides and glycoconjugates, often by the use of specific hydrolases. The usual approach for the analysis of disaccharides is HPLC of hydrolyzed disaccharides. NMR and MS are indispensable in modern structural analysis of carbohydrates.

### Methods Used in Polysaccharide Analysis

The requirements of polysaccharide analysis are essentially similar to those of oligosaccharides. Thus, many types of analytical operation are applied that the relevant techniques will be discussed on the basis of a structural classification of the polysaccharides themselves. Apart from cellulose and its derivatives, which comprise the major components of paper, textiles, and adhesive tapes, most industrial polysaccharides are incorporated in one form or another into processed foods or used in fermentation processes. Starch predominates among these but pectins, galactomannans, galactans, and alginates are also valuable ingredients. Most of the methods employed in the analysis or characterization of polysaccharides are based upon inspection, their solubility relationships, molecular weight distribution, optical activity, and electrophoretic behavior, with subsequent determination of the monosaccharide constituents and their modes of linkage. Fundamentally important criteria of polysaccharides are their immunological behavior and response towards enzymes.

**Starch** While there are specific methods, such as the measurement of the depth of the blue iodine coloration with lipid-free (1), and degradation by enzymes (amylases) followed by sugar estimation, which make the analysis of starch a relatively straightforward procedure, the determination of starch is complicated by problems of extraction from the natural source or by the fact that, in processed foods, dextrans and other products of partial hydrolysis of starch may also be present. As all glucans are hydrolyzed to D-glucose, assay of this sugar gives a measure not only of starch but also of accompanying compounds containing bound glucose unless the hydrolysis had been accomplished by specific enzymes, the most popular method today. Similarly, methods based upon measurement of optical rotation of starch ( $[\alpha]_D \sim +200^\circ$ ) solutions are entirely reliant upon the known presence or absence of other chiral substances, and upon the degree to which the natural starch granules have been brought into solution. After moisture and ash determination, hot water affects a rough separation of the more soluble amylose and

dextrins from amylopectin. 'Starch' is extracted from cereals in calcium chloride solution, 52% aqueous perchloric acid, or moist dimethyl sulfoxide. For various other classes of foodstuff, types of extraction have been evolved to suit the nature of the material. Selective acid hydrolysis of starch, or incubation at pH 4.5–5.5 with amyloglucosidases assisted by  $\alpha$ -amylase following prior gelatinization in hot water, precedes measurement of the glucose liberated. As detailed above, reducing power, response to color reagents, or enzymatic analysis specific for D-glucose constitute methods of estimating starch when appropriate conversion factors are applied. Biosensors are now used. It is important to observe that the portion of starch that is undegraded by enzymes is regarded as a component of dietary fiber.

Whole or degraded starch is currently analyzed by SEC, by the related technique of field flow fractionation (FFF), HPLC in different forms, and by a range of physical and chemical techniques including microscopy (light and SEM), X-ray diffraction, differential scanning calorimetry, NIR and FTIR spectrometry, solid-state  $^{13}\text{C}$  NMR, and most importantly by the use of such enzymes as the  $\alpha$ - and  $\beta$ -amylases and amyloglucosidase.

**Dextrins, glucose syrups, and modified starches** Dextrins, formed on heating starch, are assayed together with the unmodified polysaccharide. The dextrin-iodine coloration is reddish brown. Glucose syrups (from starch) are extremely soluble in water, and the reducing power ('dextrose equivalent') of a sample whose moisture and ash content is known affords a measure of the length of the chain of glucose residues. Free glucose is measured by the glucose oxidase method. The molecular weight distribution, which is an important property affecting viscosity, is best measured by SEC, or by an HPLC procedure. If modification of the starch by oxidation, etherification, or esterification (e.g., phosphate formation) has been carried out, methods appropriate to the specific analyses required must be adopted.

**Water-soluble, nonstarch polysaccharides** These components accompany starch in extraction processes, and are removed if possible by bringing the solution to 80% with respect to ethanol, proteins being precipitated as well. Acid hydrolysis of a test portion of the polysaccharide indicates from a chromatographic analysis of the neutral sugars released whether glucans (usually  $\beta 1 \rightarrow 3$  and  $\beta 1 \rightarrow 4$ -linked), galactomannans, or arabinoxylans are present, while the uronic acids (galacturonic acid for pectins or gums, glucuronic for gums or pectins, mannuronic and guluronic for alginates) are useful markers for different types of acidic polysaccharide. Neutral and

acidic polysaccharides in solution are differentiated by addition of cetyltrimethylammonium bromide (Cetavlon), which complexes with acidic polysaccharides, causing flocculation. The separated precipitate is then stirred in a minimum quantity of  $1 \text{ mol l}^{-1}$  sodium chloride solution, to bring about dissociation, and the polysaccharide is regenerated by pouring into ethanol (containing acetone and ether if necessary). More often than not a range of monosaccharide and uronic acid components are detected on hydrolysis of samples of the extracted polysaccharides, in which even a program of separation procedures (selective precipitation, dialysis, or chromatographic approaches) is adopted in order to isolate reasonably homogeneous fractions for detailed study, after their initial assay by weighing.

**Insoluble, noncellulosic polysaccharides** There is a gradation in the ease of extraction of polysaccharides from cell wall or endosperm from plant sources, the harshest methods generally yielding residual, colorless cellulose that can be estimated gravimetrically. After water extraction of the sample previously washed with organic solvents, reagents that sequester calcium ions (solutions of oxalate, citrate, bicarbonate, ethylenediaminetetraacetic acid, and related amphoteric compounds) are effective in bringing pectic substances into solution. These are acidic polysaccharides and the counterion will be dictated by the cation of the salt used. Salts are then conveniently removed by dialysis against distilled water, and the retentate on being freeze-dried (lyophilized) yields the pectic material in (usually) a colorless, fibrous form that is suitable for structural analysis or utilization. The gelling properties of such products (typically from fruits, leaves, or plant stems) are normally of greatest interest. Continued extraction of plant tissue, now with dilute aqueous alkali under an atmosphere of nitrogen to prevent oxidative degeneration, brings into solution various ill-defined polysaccharide mixtures for which the traditional name of hemicellulose is used. Neutralization of the solution with acetic acid yields hemicellulose A as a precipitate, and addition of ethanol to the supernatant solution gives hemicellulose B. A third soluble fraction, hemicellulose C, results on treatment with 17.5% NaOH. In any serious study of the hemicelluloses, further separations of hemicellulosic preparations are required, such as may be effected by column chromatography, but the tendency of the extracted polysaccharides to revert to insoluble material constitutes a serious barrier to effective isolation of 'pure' products, such as acidic, arabinose-substituted  $\beta$ -D-xylans and glucomannans, both of which have a cellulose-like core.

After these successive extractions of plant material, the residual cellulose is accompanied by dark brown polyphenolic material (lignin) that (unlike the cellulose) is insoluble in 72% (m/m) sulfuric acid–water. In the course of the solvent separation scheme, often before alkali is used, the standard method of removing lignin is to bring it into solution by means of sodium chlorite solution at an adjusted pH; the delignification process opens up plant tissues, permitting more thorough extraction of carbohydrate, but also causes some degradation and must be employed with due caution. Hydrolysis of the cellulosic residue normally reveals sugars, other than glucose, such as xylose or mannose, thus providing a measure of the accompanying xylan or glucomannan.

Any systematic study of cell walls requires an  $\alpha$ -D-galacturonanase to release pectic and other matrix components. Molecular structural studies have so far progressed that elaborate models showing the various polymeric constituents in juxtaposition have been generated. After enzymatic elimination of starch and protein, hydrolysis of the residual polysaccharide and estimation of the uronic acids and monosaccharides released furnish considerable information on the composition of agricultural samples. Partial depolymerization affords the complex, well-studied rhamnogalacturonans I and II (RG-I and RG-II).

**Dietary fiber** The analysis of soluble polysaccharides that resist enzyme action in the mammalian digestive system is important as the significance of this material, termed ‘dietary fiber’, is now fully recognized.

As with most analyses of polysaccharides, definition of the substances involved is the key to the methodology adopted. Dietary fiber comprises pectic and hemicellulosic components, and excludes cellulose, which is insoluble, and most of the ingested starch. Included are the natural plant gums (complex, branched, acidic heteroglycans), seed galactomannans, and industrially produced bacterial polysaccharides that are employed as food additives to impart desirable rheological properties and to limit caloric intake. Formidable as the problem is to obtain analytical results that have meaning in a physiological context, a large body of information on the dietary fiber content of foodstuffs is available. Common to the different methods of analysis is the removal of starch and protein, by enzymes that simulate human digestion, or by the use of solvent extraction with aqueous neutral detergents (yielding NDF); residual fiber is then weighed or analyzed after hydrolysis and estimation of the monosaccharides released. Future development in nutritional studies is

largely dependent upon  $^{13}\text{C}$  labeled polysaccharides becoming available.

**Carbohydrate hydrocolloids** As hydrocolloids constitute the majority of polysaccharides encountered in industry and research, the methods of analysis that apply variously to components of this group, including starch that is strictly in a category of its own on account of the overwhelming quantities used, embrace virtually all aspects of polysaccharide analysis. Glycoconjugates require certain additional, special procedures that are considered in the section that follows this account.

Hydrocolloids are dissolved in water with warming and agitation or sonication, and precipitated by addition of alcohols (MeOH, EtOH, or propan-2-ol), acetone, or ammonium sulfate. Acidic polysaccharides form insoluble complexes with Cetavlon, the precipitate being redissolved in aqueous salt solution, and the polysaccharide recovered as the sodium salt after dialysis and freeze-drying. Freeze-dried specimens of polysaccharides generally are analyzed for C, H, N, mineral ash, sulfate, and phosphate, and tested by color reactions or spectroscopy (IR, NMR) for uronic acid, amino- and acetamidodeoxy sugar, pentose, hexose, deoxyhexose, and anhydrosugar components. Purification is performed where necessary by column chromatographic methods (size-exclusion, partition, ion-exchange, affinity). Optical rotation measurements afford an index of purity and identity, and acid hydrolysis of the sample gives a good indication of the class or classes of polysaccharide present. The composition of the polysaccharide hydrolysate is normally determined by GC, HPLC, or SFC, with derivatization where necessary.

There are more or less specific color tests for starch (iodine blue) and carrageenans (using methylene blue), and in some instances the action of enzymes is diagnostic and used in reagent kits. A relatively new approach to the assay of food gums and stabilizers, one that shows many advantages in speed and specificity, is enzyme-linked immunosorbent assay, which has a number of variants.

Classification of the polysaccharide type is achieved fundamentally by hydrolysis to identifiable sugars, and by methylation analysis, in which the cleavage products from the permethylated polysaccharide are identified and assayed, after conversion to alditol acetates, acetylated aldononitriles, or other derivatives, by GC and GC–MS. Methanolysis of the permethylated polysaccharide and conversion to TMS derivatives is an alternative. The proportions of monosaccharides and their linkage modes are deduced from the molar quantities of sugar methyl ethers derived from the processed polysaccharide

sample. The category to which the polysaccharide belongs is thus determined (Table 1).

Spectroscopic methods of analysis are invaluable, particularly  $^1\text{H}$  and  $^{13}\text{C}$  NMR, which in one- and two-dimensional and various other modes permits the assignment of most of the signals obtained from polysaccharide solutions (in water,  $\text{D}_2\text{O}$ , or DMSO) to the protons and carbon atoms involved, irrespective of the molecular weight of the polysaccharide. The units and even sequences of the sugar moieties in bacterial exopolysaccharides, which comprise regular repeating structures of from three to seven monosaccharide units, may be deduced with additional information being obtained by MS. This study is aided by preliminary depolymerization using viral lyases (bacteriophages), and in an analogous manner all other polysaccharides that can be subjected to attack by endohydrolases can be readily characterized by NMR spectroscopic analysis of the polysaccharides and their products. Anomeric proton and carbon signals are easily identified, as are non-carbohydrate moieties (pyruvate ketals, methyl ethers, acetyl, or sulfate derivatives). Though not a sensitive method, low-resolution proton spectroscopy is used as a probe for examining physical and chemical properties that underlie the palatability of foodstuffs. Relaxation times ( $T_1$  and  $T_2$ ) are used to characterize the decay rates of proton signals, which, being sensitive to molecular mobility, can differentiate solid from liquid and define the quantity, mobility, and microenvironment of water molecules/droplets in complicated matrices. Solid-state NMR using the technique of cross-polarization, magic angle spinning permits the assignment of chemical shifts (values) in crystalline amyloses and in complex food structures, selected regions of which are examined by NMR imaging.  $^{13}\text{C}$  NMR enables alginates, galactomannans, starch, agar, carrageenans, and cellulose derivatives to be identified.

Measurements of IR absorption of thin films are useful for identification with authentic samples, particularly if in addition pyrolysis and GC/IR analysis of the decomposition products is carried out. The use of specific enzymes is important in aiding the isolation of polysaccharide components from natural sources, and in producing identifiable oligosaccharides that facilitate molecular structural analysis.

**General considerations** If the purpose of analysis is to determine the molecular structure of a polysaccharide (presumed to be homogeneous) in all its detail, standard procedures require the quantitative determination of all sugar units and of their respective linkage modes, and the establishment of sequences. X-ray diffraction measurements can in many cases

supply three-dimensional information, e.g., for oriented fibers or polysaccharide gels. CD supported by NMR is applied to monitor the behavior of polysaccharides in solution.

Methods involving partial breakdown of the polysaccharide sample are of great value in elucidating sugar sequences within limited regions of the macromolecule. These methods normally involve attack at the glycosidic intersugar linkages where these are weak either because they are furanosidic or have been rendered labile by selective chemical modification of sugar residues. Graded acid or enzymatic hydrolyses yield mixtures of oligosaccharides that require separation on a sufficient scale to permit structural identification of the products. Modern equipment couples chromatographic and spectrometric instrumentation so that isolation and structure determination are accomplished in one operation. Acetolysis, methanolysis, and mercaptolysis prior to aqueous acid hydrolysis may be required. Hexose/hexose and glucuronic acid/hexose bonds are normally resistant to fission; on the other hand, those positions in a polysaccharide to which labile groups are bonded may be ascertained by comparing the analytical properties of the initial and the partially hydrolyzed ('autohydrolyzed') polysaccharides.

A widely used procedure is the Smith degradation. The polysaccharide (or glycoconjugate) is oxidized with periodate, which selectively attacks all sugar units with exposed 1,2-diol groups, then reduced with borohydride to convert the resulting aldehyde to primary alcohol groups, and given a mild acid hydrolytic treatment that must be so controlled as to leave glycosidic bonds unattached but to effect complete cleavage of the glycolaldehyde acetals (at the sites of all units that have been periodate-oxidized and reduced). All sugar units protected by, e.g., (1 $\rightarrow$ 3)- or (1 $\rightarrow$ 2,4)-linkages remain intact, and joined together if contiguous in the parent polysaccharide. Isolated sugar units are recovered as polyol (ethan-1,2-diol, or glycerol) glycosides. In this manner (1 $\rightarrow$ 3)-linked  $\beta$ -D-galactan moieties have been obtained from arabinogalactans, and erythritol glucosides from (1 $\rightarrow$ 3) (1 $\rightarrow$ 4)- $\beta$ -D-glucans. Separation of the products of Smith degradation is performed by solvent extraction, SEC, or HPLC. Other forms of selective degradation include the reductive cleavage method of Gray, whereby adjustment of the catalyst controls the extent of glycosidic breakdown by triethylsilane, and a series of related base-catalyzed degradations ( $\beta$ -eliminations) that cause the fission of substituent sugars from 0 to 4 of glycuronate esters and concomitant detachment of the degraded acidic unit from its interior sugar unit. HPLC is the usual method adopted in isolating meaningful, structural

fragments from such degradations, which, together with several other approaches to targeting uronic acid constituents, have been developed by Aspinall in the study of pectins and plant gums.

## Glycoconjugates

Glycoconjugates contain protein, lipid, or polyphenolic moieties joined to carbohydrate, and though determinations of the proportion of total carbohydrate and of the monosaccharide units, and the modes of linkage involved follow standard procedures as outlined, the overall analysis has certain other requirements. Isolation methods are frequently attended by the risk of degradation. In general, the quantities available for analysis are not large, so that the development of micromethods has been of first importance. As natural compounds glycoconjugates respond to enzymatic treatment and are frequently assayed by immunological techniques.

## Glycoproteins

Glycoproteins result from the covalent association of glycans with proteins, and may be classified according to whether the glycosyl linkage is to O or N (Table 2). N-glycosylprotein glycans are divided into three groups according to monosaccharide composition and oligosaccharide structure as high mannose (containing only Man and GlcNAc), complex (galactose, sialic acid, and Fuc in addition), and hybrid (oligomannosidic, with peripheral N-Ac lactosamine; Scheme 2) types. A given oligosaccharide located at a specific amino acid in a glycoprotein may be polymorphic due to partial substitution of sugar residues on a similar core structure, leading to a type of diversity called microheterogeneity that is common to almost all glycoproteins. Glycan structures associated with glycoproteins range from short linear chains to more highly ramified oligosaccharides with multiple (usually two to five) outer chains (Scheme 2), termed antennae.

**Table 2** The amino acid and sugar linkages engaged in carbohydrate–peptide linkages<sup>a</sup> in glycoproteins

Amino acid	Linkage type	Corresponding sugar
L-Asparagine	N	2-Acetamido-2-deoxy-D-glucose
L-Threonine	O	2-Acetamido-2-deoxy-D-galactose
L-Serine	O	2-Acetamido-2-deoxy-D-galactose or 2-acetamido 2-deoxy-D-xylose
5-Hydroxy-L-lysine	O	D-Galactose

<sup>a</sup> A glycoprotein may exhibit both O and N linked chains.

Glycoproteins are widely distributed in animals, plants, microorganisms, and viruses, in which the glycans perform a range of important biological roles particularly in respect of intercellular recognition and adhesion. The glycan structure of the cell membrane glycoproteins (and glycolipids) is profoundly altered in cancer cells leading to the appearance of cell surface neoantigens that could be a factor in cancer induction and metastatic diffusion. Proteoglycans are a large subgroup of glycoproteins that consist of a central core protein to which are attached a number of long, highly charged glycosaminoglycan (GAG) chains, which confer exceptional water-holding properties. Proteoglycans are high molecular weight, unbranched heteropolymeric molecules consisting of repeating disaccharides (4-linked uronic acid to 3- or 4-linked acetamidodeoxyhexose; (21) and (22)) substituted with sulfate ester groups, and are distributed ubiquitously throughout the extracellular matrices of connective tissues. A range of plant proteoglycans and glycoproteins occurs in plant cell walls, many of them cross-linked in the matrix, so that treatment with cold, anhydrous HF is invaluable in effecting their isolation. The arabinogalactan-proteins (AG-Ps) are, however, water-soluble, and many enzymes, lectins, and the cell wall component extension may be extracted directly into aqueous NaCl.

Glycoproteins are purified using methods based on precipitation with ethanol or various salts, and by chromatographic (SEC, ion-exchange, hydrophobic interaction, HPLC) and electrophoretic techniques. The two latter techniques have been extensively exploited in mapping N-linked glycans and glycopeptides by two- and even three-dimensional techniques, the unique significance of sugar sequences in biological recognition events being generally understood. Lectin-affinity chromatography is used extensively

to separate glycoproteins according to their glycan composition. Prior to analysis of the oligomers in glycoproteins it is essential that they be split off from the protein core. This is achieved enzymatically with endo-glycosidases, or chemically with trifluoromethane sulfonic acid, alkaline sodium borohydride, hydrazine, or anhydrous HF. O- but not N-glycosidic bonds are cleaved at room temperature with the last-named reagent, and by operating at temperatures down to  $-23^{\circ}\text{C}$ , selective fission of glycosidic bonds may be achieved.

Kits for analyzing glycoproteins are now available, utilizing recombinant endo-enzymes together with electrophoresis and fluorescent labeling with ANTS (aminonaphthalene-1,3,6-trisulfonic acid); PMP (1-phenyl-3-methyl-5-pyrazolone), or other, similar type of reagent can be used. MS plays a crucial role in glycopeptide characterization where techniques such as electrospray LC-MS and MALDI-TOF MS are utilized.

The analytical procedures applied to glycoconjugates are essentially those described for pure glycans. In most instances, however, only minute quantities of carbohydrate are available, and the enhancement of detection sensitivity (to the picogram level) by incorporation of a radioactive or fluorogenic label is essential. HPLC with fluorimetric or pulsed amperometric detection is used extensively, and modern developments in MS (e.g., electrospray ionization MS-MS) are especially applicable. NMR using computerized databanks are of outstanding importance, and as an example of the exceptional power of the method, high-resolution magic-angle spinning NMR can detect and characterize O-specific polysaccharide components of the cell wall on the surface of 'living' bacteria. Given larger amounts of material such as cartilage or skin, the unique structural feature of alternating 3-linked and 4-linked sugar units of the type present in some GAGs (21) enables the processes of Smith degradation (cf. cereal  $\beta$ -D glucans) and  $\beta$ -elimination (22) using mild alkali to be used to good effect. Lyases, or the use of mild alkali, also cause fission of the 4-O-glycosyl substituent from the uronic acid chain units of (21) and (22), producing double bonds that are easily detectable.

## Glycolipids

Glycolipids are distributed throughout animal, plant, and microbial cells. The glyco-components, linked to ceramide or other glycerol derivatives, are mono- or oligosaccharide chains that are frequently branched, and may be substituted with acetyl or sulfate groups. The precise carbohydrate structures, including, e.g., the presence or absence of sialic acid, confer

biological specificity on glycolipids. The extraction of glycolipids is generally achieved by Folch procedure, in which fresh tissue is homogenized with chloroform/methanol and the insoluble material is removed by filtration or centrifugation. The crude glycolipid extract may then be purified using a number of chromatographic techniques including ion exchange, silica gel, TLC, HPLC, and SFC methods.

A considerable amount of information regarding the glycan structures of glycolipids may be obtained by a combination of methylation and mass spectral analysis of the intact molecule. Sialic acids are easily removed, and oligosaccharide chains may be cleaved from the lipid portion either chemically or enzymatically with a specific endo-glycoceramidase.

## Sugars – Spectrophotometric Methods

### Introduction

Analysis of sugars is a crucial aspect of carbohydrate chemistry, not only because of the economic importance of certain sugars, such as glucose, fructose, and sucrose in, for example, the food industry, but also because structural studies of polysaccharides and glycoconjugates require identification and quantitation of the constituent monosaccharides. Mixtures of sugars are usually analyzed by chromatographic methods. However, spectrophotometric methods also play an important role, as pre- or postcolumn derivatization is often employed to enhance sensitivity in qualitative and quantitative analysis of sugars by liquid chromatography (LC). In this article, emphasis is laid on the use of ultraviolet (UV)–visible spectrophotometry and fluorimetry for that purpose. The standard methods for detection and determination of carbohydrates are described elsewhere.

### Precolumn Derivatization for LC of Sugars

#### For UV Detection

Hydroxyl groups of sugars are points of substitution for chromophoric aryl groups, the chromophores being introduced by formation of ester or ether

linkages. Benzoylation has been widely employed for precolumn derivatization of sugars to be analyzed by LC on unmodified silica or in reversed-phase mode. Benzoyl chloride in pyridine was initially used as the derivatizing agent, but subsequently the preferred reagent has been benzoic anhydride, catalyzed by 4-dimethylaminopyridine; this is especially the case where amino sugars are present in the mixture to be analyzed, since some *N*-benzoylation occurs with benzoyl chloride. To obviate problems arising from the production of multiple peaks by anomeric pairs and pyranose/furanose isomers, sugars are often reduced to the corresponding alditols (by treatment with sodium borohydride) before benzoylation. Benzoylates of sugars are usually detected and determined after LC by UV photometry at 230 or 254 nm, although 275 nm has been the wavelength generally used in detection of benzoylated alditols.

4-Nitrobenzoylation has been used as a derivatization method by some in preference to benzoylation, since the incorporation of the additional chromophoric group produces a 10-fold increase in the sensitivity of UV detection. The derivatizing agent is 4-nitrobenzoyl chloride in pyridine, and the derivatives are detected by UV photometry at 260 nm.

Conversion of reducing sugars to hydrazone derivatives is also an effective method of introducing chromophoric groups. Precolumn derivatization to 2,4-dinitrophenylhydrazones has been recommended for LC analysis of the neutral sugar components of glycoproteins, as the reagent is selective for these, with no interference from amino sugars, uronic acids,

### Introduction

Analysis of sugars is a crucial aspect of carbohydrate chemistry, not only because of the economic importance of certain sugars, such as glucose, fructose, and sucrose in, for example, the food industry, but also because structural studies of polysaccharides and glycoconjugates require identification and quantitation of the constituent monosaccharides. Mixtures of sugars are usually analyzed by chromatographic methods. However, spectrophotometric methods also play an important role, as pre- or postcolumn derivatization is often employed to enhance sensitivity in qualitative and quantitative analysis of sugars by liquid chromatography (LC). In this article, emphasis is laid on the use of ultraviolet (UV)–visible spectrophotometry and fluorimetry for that purpose. The standard methods for detection and determination of carbohydrates are described elsewhere.

### Precolumn Derivatization for LC of Sugars

#### For UV Detection

Hydroxyl groups of sugars are points of substitution for chromophoric aryl groups, the chromophores being introduced by formation of ester or ether

linkages. Benzoylation has been widely employed for precolumn derivatization of sugars to be analyzed by LC on unmodified silica or in reversed-phase mode. Benzoyl chloride in pyridine was initially used as the derivatizing agent, but subsequently the preferred reagent has been benzoic anhydride, catalyzed by 4-dimethylaminopyridine; this is especially the case where amino sugars are present in the mixture to be analyzed, since some *N*-benzoylation occurs with benzoyl chloride. To obviate problems arising from the production of multiple peaks by anomeric pairs and pyranose/furanose isomers, sugars are often reduced to the corresponding alditols (by treatment with sodium borohydride) before benzoylation. Benzoates of sugars are usually detected and determined after LC by UV photometry at 230 or 254 nm, although 275 nm has been the wavelength generally used in detection of benzoylated alditols.

4-Nitrobenzoylation has been used as a derivatization method by some in preference to benzoylation, since the incorporation of the additional chromophoric group produces a 10-fold increase in the sensitivity of UV detection. The derivatizing agent is 4-nitrobenzoyl chloride in pyridine, and the derivatives are detected by UV photometry at 260 nm.

Conversion of reducing sugars to hydrazone derivatives is also an effective method of introducing chromophoric groups. Precolumn derivatization to 2,4-dinitrophenylhydrazones has been recommended for LC analysis of the neutral sugar components of glycoproteins, as the reagent is selective for these, with no interference from amino sugars, uronic acids,

alditols, or amino acids. The recommended reagent is a solution of 2,4-dinitrophenylhydrazine (1.5%, m/v) in 1,2-dimethoxyethane. The reaction is acid-catalyzed and therefore a 2% (v/v) solution of trifluoroacetic acid in methanol is also added to the sugar mixture. The mixture is heated at 65°C for 90 min, cooled, and then excess 2,4-dinitrophenylhydrazine is precipitated by addition of acetone. The sugar derivatives are extracted into 1,2-dimethoxyethane for LC analysis, the peaks being recorded at 352 nm.

Reductive amination is widely used as a means of introducing chromophoric or fluorescent groups into sugars. Aldose sugars are converted to acyclic imines by reaction with the amine in the presence of an acid catalyst, and the imines produced are reduced to secondary amines by treatment with sodium cyanoborohydride. The formation of multiple peaks is prevented by this method of derivatization. Reductive amination with 4-aminobenzoic acid ethyl ester (ABEE) is very effective in increasing the sensitivity of detection of sugars in reversed-phase high-performance liquid chromatography (HPLC). The UV absorption maximum for such derivatives is at 229 nm, but the 254 nm of a standard UV photometer is often adequate for their detection. There is another absorbance peak at 304 nm. The derivatization reagent is usually prepared by mixing ABEE ( $470 \mu\text{g} \mu\text{l}^{-1}$ ), sodium cyanoborohydride ( $100 \mu\text{g} \mu\text{l}^{-1}$ ), and acetic acid (11.7%, v/v) in warm methanol. For analysis of sugars at picomolar level this reagent ( $40 \mu\text{l}$ ) is heated with the sample at 80°C for 1 h in a sealed tube. The reaction mixture is then cooled to room temperature and vortexed with a 1:1 mixture of water and chloroform (0.4 ml) to remove excess reagent. The upper, mainly aqueous, layer is used in HPLC.

Reductive amination of aldoses with chiral L-(–)- $\alpha$ -methylbenzylamine in the presence of sodium cyanoborohydride, carried out overnight at room temperature, followed by acetylation with acetic anhydride in pyridine (100°C, 1 h) gives diastereoisomeric 1-(N-acetyl- $\alpha$ -methylbenzylamino)-1-deoxyalditol acetates. LC of these derivatives on silica gel permits resolution of enantiomeric pairs, which are detected by UV photometry at 230 nm.

### For Fluorimetric Detection

Sensitivity of detection in LC of sugars is greatly enhanced by the introduction of a fluorescent group, thus permitting the use of fluorimetric detection. A reagent frequently employed for this purpose is 5-dimethylaminonaphthalene-1-sulfonyl hydrazine (dansyl hydrazine). The reagent solution (1%, m/v, in

ethanol or 5% in acetonitrile) is added to the sugars in the presence of trichloroacetic acid as a catalyst (0.5%, m/v, in ethanol, 10% in acetonitrile) and the mixture is heated at 50°C for 90 min. The derivatized sugars are detectable at picomolar levels by fluorimetry (excitation wavelength 350 nm, emission 500 nm). More recently, detection at subpicomolar levels has been reported in LC of sugars following reduction to the alditols and reaction with 2-naphthoylimidazole, with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) as a catalyst. The pernapthoates are detected down to levels of  $\sim 0.1 \text{ pmol}$  by fluorimetry (excitation wavelength 234 nm, emission 374 nm).

Reductive amination is probably the method most widely used today for the introduction of fluorescent groups into sugars prior to analysis by chromatographic or electrophoretic methods. The fluorescent derivatives thus produced can also be detected by UV absorption, and this is sometimes preferred where the analytes are present at higher concentrations as, in contrast to fluorimetric detectors, the response of UV detectors remains linear over a wide range. However, if only trace amounts are to be analyzed, fluorimetry is the method of choice, as in most cases the derivatives are detectable at picomolar or even femtomolar levels under these conditions.

The reagent that has been most used for fluorogenic labeling of sugars and, especially, the complex oligosaccharides produced in degradative studies of glycoconjugates is 2-aminopyridine. Reductive amination with this reagent can be applied to amino sugars and sialic acids as well as neutral sugars, and this permits simultaneous analysis of, for example, the monosaccharide components of glycoproteins by reversed-phase HPLC with fluorimetric detection (excitation wavelength 320 nm, emission 400 nm) in the concentration range 10 pmol to 10 nmol. Glycoconjugates have been analyzed by this method using samples of only 100–200 pmol (glycoproteins) or 1–2  $\mu\text{g}$  (glycolipids). The reagent recommended by Hase, Takemoto, and co-workers is an aqueous solution (pH 6.2) of 2-aminopyridine (4.5%, m/v) containing hydrochloric acid (3.6%, v/v), which remains stable for at least a year if stored at  $-20^\circ\text{C}$ . The reagent ( $5 \mu\text{l}$  for analysis at picomolar level) is added to the dry sample and the mixture is heated at 100°C for 15 min in a sealed tube. The reducing agent, a freshly prepared aqueous solution of sodium cyanoborohydride ( $20 \text{ mg ml}^{-1}$ ,  $2 \mu\text{l}$ ) is then added, the tube is resealed, and heating is continued at 90°C for 8 h. Before HPLC analysis the excess reagents and by-products are removed by size-exclusion chromatography on a column of low porosity, with a solution containing a volatile salt

(such as ammonium acetate) as eluent. The 2-amino-pyridyl derivatives can also be used in nuclear magnetic resonance and mass spectrometry (MS) studies.

In recent years, several new fluorogenic reagents have been introduced for labeling of sugars and other carbohydrates by reductive amination prior to reversed-phase HPLC, often coupled to MS, since these derivatives give highly characteristic mass spectra. The derivatization process has been simplified by reaction of the analytes with the amine and the reducing agent (the borane–dimethylamine complex is now sometimes used instead of sodium cyanoborohydride) in a single step, as in the case of the reaction with ABEE mentioned before. For example, the reagent recommended by Anumula for reductive amination with 2-aminobenzoic acid (anthranilic acid) consists of a mixture of anthranilic acid (30 mg ml<sup>-1</sup>) and sodium cyanoborohydride (20 mg ml<sup>-1</sup>) in methanol containing acetic acid (2%, v/v). The sample is heated with this reagent at 80°C for 1 h and the products are purified by vortexing with the (mainly aqueous) mobile phase used in HPLC. Fluorimetric detection (excitation wavelength 230 nm, emission 425 nm) permits detection of the sugar derivatives (both neutral and amino sugars in glycoprotein hydrolysates) at femtomolar levels, so that analyses can be performed with glycoprotein samples of less than 1 µg.

Other reagents used for this purpose include 2-aminoacridine (AMAC), which gives acridone derivatives that are uncharged at the pH used in HPLC and are therefore suitable for the separation of both neutral and acidic oligosaccharides. Fluorimetry (excitation wavelength 428 nm, emission 525 nm) makes possible detection at subpicomolar levels. Reductive amination with 8-aminonaphthalene-1,3,6-trisulfonic acid (ANTS) has also been widely adopted recently as a technique for derivatization of sugars before reversed-phase HPLC or capillary electrophoresis. These derivatives can be detected by UV at 300 nm but fluorimetry (excitation wavelength 370 nm, emission 515 nm) allows detection to levels of ~0.2 pmol. The technique has been applied in the analysis of small amounts of sugar chains from glycoproteins.

The specificity and sensitivity of some of the detection methods discussed in this section are summarized in Table 1.

## Postcolumn Derivatization

The rapid development of HPLC/MS, for which the derivatives mentioned in the previous section are very suitable, has led to decreased use of postcolumn derivatization in LC of carbohydrates. Nevertheless, such methods do have certain advantages, apart from

**Table 1** Specificity and sensitivity of precolumn derivatization methods for sugars

<i>Method</i>	<i>Specificity</i>	<i>Detection limit</i>
Benzoylation	All carbohydrates	1–10 nmol
4-Nitrobenzoylation	All carbohydrates	0.1–1 nmol
Formation of 2,4-dinitro-phenylhydrazones	Reducing sugars	50 pmol
Formation of dansyl-hydrazones	Reducing sugars	3–5 pmol <sup>a</sup>
As alditol pernapthoates	Reducing sugars	0.1 pmol <sup>a</sup>
Reductive amination	Reducing sugars	
With ABEE		0.5 nmol
With 2-aminopyridine		10 pmol <sup>a</sup>
With anthranilic acid		100 fmol <sup>a</sup>
With ANTS or AMAC		0.2 pmol <sup>a</sup>

<sup>a</sup>With fluorimetric detection.

the obvious one of direct injection of sugars into the chromatograph: it has been noted that, with careful standardization, the formation of artifacts is of minor significance and the derivatization reactions do not necessarily have to be completed or fully defined. Thus, postcolumn derivatization methods with spectrophotometric or fluorimetric detection remain useful in carbohydrate analysis.

The various reactions applied for this purpose can be classified into the same main types as the chromogenic reagents used to visualize sugars in thin-layer chromatography. In addition, there are certain reactions of other types that have been adapted for LC detection systems. The different kinds of reaction used are described and exemplified below.

## Production of Furfural Derivatives

The classical methods for quantitative analysis of carbohydrates were based mainly on the formation of colored products on treatment of the analytes with strong mineral acids and condensation of the resulting 2-furaldehyde (furfural) derivatives with a suitable chromogenic reagent (usually a phenol or aromatic amine). Examples include the well-known procedures involving the use of sulfuric acid with phenol, orcinol, cysteine, or anthrone.

The phenol–sulfuric acid method involves treatment of the solution containing the carbohydrate analyte (5–40 µg ml<sup>-1</sup>) with an aqueous solution of phenol (5%, m/v) and then concentrated sulfuric acid: a characteristic yellow color is produced, with an absorption maximum at 490 nm for hexoses, 480 nm for pentoses, deoxy sugars, and uronic acids. Only amino sugars do not react. Oligo- and polysaccharides are hydrolyzed to their constituent monosaccharides by the addition of concentrated

sulfuric acid, which generates a great deal of heat, and therefore they can also be analyzed in this way. This long-established method has proved very effective in manual analyses of carbohydrates. However, adaptation of the procedure to automation in LC systems poses problems due to the excessive heat and pulsing produced when the acid is mixed with the aqueous effluent from the column.

The orcinol–sulfuric acid method, in which the recommended reagent is a solution of orcinol (0.1%, m/v) in diluted sulfuric acid (70%, v/v), was the first to be adapted for use in an automated carbohydrate analyzer. After mixing with the reagent, the column effluent is heated at 95°C for 15 min. Absorbance is usually measured at 420–425 nm; however, measurement at two wavelengths (420 and 510 nm) has been recommended where deoxy sugars or uronic acids are present.

The cysteine–sulfuric acid method, with a reagent consisting of a solution of cysteine (0.07%, m/v) in 86% (v/v) sulfuric acid, has also been successfully automated. The reagent is mixed with the column effluent in a ratio of 5:1 (v/v) and this is followed by heating at 97°C for 3 min. The absorption maximum of the colored derivative ranges from 390 nm (pentoses and uronic acids) through 400 nm (6-deoxyhexoses) to 412–414 nm (hexoses) and therefore the measurement of absorbance at more than one wavelength in this range has been recommended.

Anthrone (9,10-dihydro-9-oxo-anthracene) reacts with most carbohydrates in concentrated sulfuric acid to produce a characteristic blue color, with an absorption maximum at 625 nm. This reaction has been automated and was once widely used in analysis of dextran fractions emerging from size exclusion columns. However, as in the case of the phenol–sulfuric acid method, the presence of concentrated acid necessitates special precautions (such as the inclusion of a pulse suppressor) and for this reason, and also because of the instability of the reagent, the method is seldom used today except in manual analysis.

In addition to the reactions mentioned above, there are others of this type that are used in detecting and determining specific classes of carbohydrates. The carbazole–sulfuric acid method has been much used in analysis of uronic acids and acidic polysaccharides, which give a weaker response than neutral sugars in the other methods. The presence of borate ions decreases interference by proteins and salts, increases color yield, and reduces the time required for color development. In a recommended procedure for manual analysis, the sample solution (containing 0.02–0.2  $\mu\text{mol}$  of uronic acid) is mixed (1:5, v/v) with a solution of sodium tetraborate (25  $\text{mmol l}^{-1}$ ) in concentrated sulfuric acid and the mixture is heated at 100°C for 10 min. After rapid

cooling to 4°C the reaction mixture is mixed (30:1, v/v) with a solution of carbazole (0.125%, m/v) in ethanol. Heating at 100°C is continued for a further 15 min and, after cooling to room temperature, the absorbance at 530 nm is measured. The procedure has been successfully automated.

As there is some interference from hexoses and, to a lesser extent, pentoses in this analytical method, it has been recommended that for analysis of uronic acids in the presence of neutral sugars in appreciable proportion the carbazole should be replaced by 3-hydroxydiphenyl. In this case the sample (containing 0.5–20  $\mu\text{g}$  of uronic acid) is mixed (1:6, v/v) with a solution of sodium tetraborate (12.5  $\text{mmol l}^{-1}$ ) in concentrated sulfuric acid and, after heating at 100°C for 5 min and cooling to 4°C, 20  $\mu\text{l}$  of the reagent (3-hydroxydiphenyl, 0.15%, m/v, in 0.5% NaOH) is added. Absorbance at 520 nm should be measured within 5 min of mixing. As neutral sugars at high concentration produce a pale pink color with  $\text{Na}_2\text{B}_4\text{O}_7\text{--H}_2\text{SO}_4$  at 100°C, the absorbance of a blank, in which the reagent is replaced by 20  $\mu\text{l}$  of 0.5% NaOH, should be subtracted from the reading. This method is more sensitive and specific than the carbazole method. The molar absorptivity of the chromophore produced by mannuronic acid is  $\sim 50\%$  of that of the product from glucuronic acid, but the other uronic acids commonly encountered, i.e., galacturonic and iduronic acids, give absorbances only slightly below that given by glucuronic acid.

The resorcinol–hydrochloric acid method is specific for ketoses or other carbohydrates containing keto groups, such as sialic acids. In an automated method that has proved useful in chromatographic analysis of commercial syrups containing fructose in the presence of glucose and other aldoses, the column effluent is mixed 1:5 (v/v) with the reagent (resorcinol, 0.05%, m/v, in concentrated HCl) and the mixture 20:1 (v/v) with an aqueous solution of 1,1-diethoxyethane (0.05%, m/v) and heated at 95°C for 3 min. The absorbance of the product is measured at 550 nm.

The necessity for corrosive acids in the analytical system is a serious drawback of all methods of this type when utilized in automated LC systems. Nevertheless, postcolumn derivatization based on these principles remains important because it allows the simultaneous analysis of reducing and nonreducing carbohydrates. Most of the noncorrosive reagents that are used under neutral or mildly alkaline conditions (discussed next) are applicable only to reducing sugars.

### Reactions Involving Reduction by Sugars

Some metallic cations, such as iron(III) and copper(II), are easily converted to lower oxidation states

in the presence of reducing sugars. Therefore, if the system contains ligands that are incapable of interacting with the cations in the higher oxidation state but can bind to the reduced metal ions to form chelates having absorption maxima in the UV or visible region, spectrophotometric determination of the reducing sugars is possible. A prime example is the copper–bicinchoninate method, which is based on the formation of a deep lavender complex between Cu(I) and 2,2′-bicinchoninate. In this method an aqueous solution containing  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  (0.1%, m/v), with aspartic acid (0.37%, m/v) as a masking agent, is mixed 1:1 (v/v) with a solution of disodium 2,2′-bicinchoninate (0.2%, m/v) in 0.38% (m/v)  $\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$  ( $0.133 \text{ mol l}^{-1}$ ) to produce the reagent. In an automated system the column effluent is mixed (2:1, v/v) with the reagent and, after heating at  $100^\circ\text{C}$  for 5 min, the absorbance of the colored product is measured at 562 nm. The detection limits for most sugars, including amino sugars and uronic acids as well as neutral sugars, are in the range of 100–200 pmol.

Another method based on the reducing power of sugars is that in which 4-anisyltetrazolium chloride (tetrazolium blue) is reduced to diformazan in alkaline solution. This is not applicable to systems using aqueous eluents, in which the product precipitates, but can be used with eluents consisting largely of ethanol or acetonitrile, where it is freely soluble. An automated system has been described in which the reagent, a solution of tetrazolium blue (0.2%, m/v) in NaOH ( $0.18 \text{ mol l}^{-1}$ ), is mixed (2:5, v/v) with the column effluent and heated at  $80^\circ\text{C}$  for 1 min. The absorbance of the product is measured at 520 nm. The method is highly sensitive, detection limits being of the order of 100 pmol for neutral sugars.

### Periodate Oxidation

Carbohydrates containing vicinal diol systems are oxidized by periodate, and there are analytical methods that are based on reaction of the products with chromogenic reagents. The classic example is the Hantsch reaction, in which the formaldehyde produced on oxidation with sodium metaperiodate is reacted with 2,4-pentanedione in the presence of ammonia to give a pyridine derivative with an absorption maximum at 412 nm. However, this is applicable mainly to alditols; aldoses give a much lower response. A generally more useful method involves monitoring the elution of carbohydrate in aqueous HPLC systems by continuous measurement of the periodate consumption of the effluent, on the basis of the decrease in UV absorbance that accompanies reduction of periodate to iodate. A reagent consisting of  $\text{NaIO}_4$  ( $1 \text{ mmol l}^{-1}$ ) in borate buffer ( $0.5 \text{ mol l}^{-1}$ ,

pH 8.6) has been recommended, with heating at  $90^\circ\text{C}$  for 5 min. The absorbance maximum for iodate is at 223 nm, but the loss in sensitivity at the standard 254 nm of simple photometers is marginal. The method is applicable not only to alditols but also to sugars, both reducing and nonreducing, with detection limits in the nanomolar range.

### Condensation with Hydrazino Compounds

Reactions of reducing carbohydrates with hydrazides of benzoic acid derivatives in strong alkali give a yellow color, believed to be due to the formation of the anionic forms of carbohydrate hydrazones. This affords a sensitive analytical method, which can also be applied to nonreducing oligosaccharides if they are first hydrolyzed to reducing sugars by passage of the analyte solution at elevated temperatures through a cation-exchange resin in the hydrogen form. In a detection method for sugars in aqueous media a reagent prepared by mixing a solution of 4-hydroxybenzoic acid hydrazide (5%, m/v) in hydrochloric acid ( $0.5 \text{ mol l}^{-1}$ ) 10:57 (v/v) with NaOH ( $0.75 \text{ mol l}^{-1}$ ) is mixed 1:2 (v/v) with the column effluent and, after heating at  $95^\circ\text{C}$  for 40 s, the absorbance of the product is measured at 410 nm. The amino analog of this reagent, 4-aminobenzoic acid hydrazide (ABH), has proved to be even more sensitive to sugars. The reagent, prepared by mixing a stock solution, of the same concentration and HCl content as that given above for the hydroxy compound, with  $2.4 \text{ mol l}^{-1}$  NaOH in a ratio of 1:2 (v/v), must be clarified by ultrafiltration and sonication before use. The other analytical conditions are the same. Detection limits for reducing sugars, and for sucrose if the catalytic resin column is used, are of the order of 40 pmol. This has been shown to be one of the most sensitive of all the postcolumn derivatization methods for sugar analysis.

### Specific Methods for Amino Sugars

Amino sugars give lower responses or do not react at all in many of the analytical methods that have been described. Analyses for these sugars are generally based on the reaction of the amino groups with ninhydrin, the reagent used in the standard amino acid analyzer. This type of system may therefore be applied to the quantitative determination of amino sugars, with detection at 570 nm. Greater sensitivity is possible, however, if the ninhydrin reagent is replaced by 2-phthalaldehyde, which is used in alkaline solution in the presence of ethanethiol or 2-mercaptoethanol. This commercially available reagent produces fluorescent 1-alkylthio-2-alkyl-substituted isoindoles with amino sugars, which permits fluorimetric detection

(excitation wavelength 340 nm, emission 455 nm), with detection at levels down to 3 nmol. Amino acids interfere, but are readily separated from the sugar derivatives by cation-exchange chromatography.

### Reactions with Fluorogenic Reagents

The use of fluorogenic reagents in postcolumn derivatization of sugars can result in detection at picomolar levels. Among the reagents that have been successfully used for this purpose are simple aliphatic amines. In a weakly alkaline medium at elevated temperatures reducing sugars react with ethylenediamine to give fluorescent products resulting from isomerization of the sugars (Lobry de Bruyn–van Ekenstein reaction) and reaction of the intermediates with excess amine. This was first suggested as a sensitive detection method for sugars analyzed by borate anion-exchange chromatography, ethylenediamine ( $7.5 \text{ mmol l}^{-1}$ ) being added postcolumn to the mobile phase (borate buffer,  $0.7 \text{ mol l}^{-1}$ , pH 8.6) used in this chromatographic method. The optimal

reaction temperatures were found to be 110–120°C for pentoses, 120–130°C for hexoses (including hexuronic acids), and 140–145°C for heptoses and simple oligosaccharides (cleaved to monosaccharides by alkaline hydrolysis under the conditions used). Fluorimetry (excitation wavelength 360 nm, emission 455 nm) gave detection limits in the range 100–400 pmol for most reducing sugars. The ethylenediamine reagent can be used with any aqueous eluent under the appropriate pH conditions (which can be adjusted postcolumn) but is not satisfactory with organic eluents. As the products of derivatization are oxidizable, the reagent can also be used with electrochemical detection at a glassy carbon electrode, under which conditions even higher sensitivity is possible.

Ethanolamine is another alkylamine that reacts with reducing sugars to give fluorescent products. An aqueous solution containing boric acid and ethanolamine (both 2%, m/v) is used as the reagent and is mixed 1:3 (v/v) with the column effluent, at a temperature of 150°C, with fluorimetric detection of the products (excitation wavelength 357 nm,

**Table 2** Specificity and sensitivity of postcolumn derivatization methods for sugars

Method	Specificity	Detection limit <sup>a</sup>
<i>Production of furfural derivatives</i>		
Anthrone–H <sub>2</sub> SO <sub>4</sub>	Neutral sugars	100 nmol
Carbazole–H <sub>2</sub> SO <sub>4</sub>	Uronic acids	25 nmol
Cysteine–H <sub>2</sub> SO <sub>4</sub>	Neutral sugars, uronic acids	25–50 nmol
Orcinol–H <sub>2</sub> SO <sub>4</sub>	Neutral sugars, uronic acids	20–40 nmol
Phenol–H <sub>2</sub> SO <sub>4</sub>	Neutral sugars, uronic acids	20–40 nmol
Resorcinol–HCl	Ketoses	40–50 nmol
<i>Use of reducing power</i>		
Cu <sup>2+</sup> -2,2'-bicinchoninate	Reducing sugars	100–200 pmol
Tetrazolium blue	Neutral reducing sugars	50–200 pmol
<i>Periodate oxidation</i>		
NaIO <sub>4</sub>	Sugars with vicinal diol systems	1–10 nmol
<i>Condensation with hydrazides</i>		
4-Hydroxybenzoic acid hydrazide	Neutral reducing sugars	20 nmol
4-Aminobenzoic acid hydrazide	Neutral reducing sugars	40 pmol
<i>Specific for amino sugars</i>		
Ninhydrin	Sugars with primary amino groups	25 nmol
2-Phthaldehyde 3 nmol (fluorimetric detection)		3 nmol
<i>With fluorogenic reagents</i>		
Ethanolamine–boric acid (fluorimetric detection)	Neutral reducing sugars	1–5 nmol
Ethylenediamine	Neutral reducing sugars	
Fluorimetric detection		100–400 pmol
Amperometric detection		1 pmol
2-Cyanoacetamide	All reducing aldoses	Neutral sugars
UV detection		0.1–1 nmol; uronic acids 0.2–0.8 nmol; aminodeoxy sugars 2–3 nmol; acetamidodeoxy-hexoses 400 pmol
Fluorimetric detection		0.25 nmol; uronic acids 50–120 pmol; aminodeoxy sugars 2–3 nmol

<sup>a</sup>UV–visible spectrophotometric detection, except where otherwise indicated.

emission 436 nm). This reagent has been used successfully with both aqueous and acetonitrile-rich eluents. Detection limits are below 5 nmol for monosaccharides, but higher for oligosaccharides, the response decreasing sharply with increasing degree of polymerization and hence reducing power. Sensitivity for oligosaccharides (nonreducing as well as reducing) can be improved by online postcolumn hydrolysis with 4-toluenesulfonic acid prior to the reaction.

The most versatile of the fluorogenic reagents that have been used in sugar analysis is 2-cyanoacetamide, which reacts with reducing aldoses in weakly alkaline solutions at elevated temperatures to give intensely fluorescent compounds (excitation wavelength 331 nm, emission 383 nm). Like ethylenediamine, this reagent was originally employed in borate anion-exchange chromatography of sugars, where an aqueous solution (10%, m/v) was mixed 1:1 (v/v) with borate buffer (0.5–0.6 mol l<sup>-1</sup>, pH 9.0) before being added to the column effluent and heated at 100°C. The reagent may also be applied with acetonitrile-rich eluents, in which case a concentration of 5% (m/v) in potassium borate (0.1 mol l<sup>-1</sup>, pH 10.4) has been recommended, with a higher reaction temperature (135°C) to prevent the precipitation of borate salts on mixing with the organic eluent. The sensitivity is greater under these conditions (detection limit ~250 pmol for all neutral aldoses). Detection with 2-cyanoacetamide has been successfully applied not only to neutral sugars but also to uronic acids, amino sugars, and the monosaccharide constituents of glycoproteins (including acetamido-deoxyhexoses and sialic acids), as well as to alditols. The fluorescent products of the reaction of 2-cyanoacetamide with reducing aldoses are believed to be 3-cyano-2-pyridone and 3-cyano-2-pyrrolidone derivatives, and there is also a product, containing a conjugated diene system in the molecular structure, which absorbs strongly at 270 nm, so that UV detection is also sensitive. As all of these products are readily oxidizable at a glassy carbon electrode, electrochemical detection is another option with this useful analytical reagent.

The specificity and sensitivity of the reagents discussed in this section are summarized in Table 2.

## Sugars – Chromatographic Methods

**S C Churms**, University of Cape Town, Rondebosch, South Africa

## Introduction

Chromatographic analysis of samples containing mixtures of sugars is an essential operation in any laboratory concerned with carbohydrates, whether

emission 436 nm). This reagent has been used successfully with both aqueous and acetonitrile-rich eluents. Detection limits are below 5 nmol for monosaccharides, but higher for oligosaccharides, the response decreasing sharply with increasing degree of polymerization and hence reducing power. Sensitivity for oligosaccharides (nonreducing as well as reducing) can be improved by online postcolumn hydrolysis with 4-toluenesulfonic acid prior to the reaction.

The most versatile of the fluorogenic reagents that have been used in sugar analysis is 2-cyanoacetamide, which reacts with reducing aldoses in weakly alkaline solutions at elevated temperatures to give intensely fluorescent compounds (excitation wavelength 331 nm, emission 383 nm). Like ethylenediamine, this reagent was originally employed in borate anion-exchange chromatography of sugars, where an aqueous solution (10%, m/v) was mixed 1:1 (v/v) with borate buffer (0.5–0.6 mol l<sup>-1</sup>, pH 9.0) before being added to the column effluent and heated at 100°C. The reagent may also be applied with acetonitrile-rich eluents, in which case a concentration of 5% (m/v) in potassium borate (0.1 mol l<sup>-1</sup>, pH 10.4) has been recommended, with a higher reaction temperature (135°C) to prevent the precipitation of borate salts on mixing with the organic eluent. The sensitivity is greater under these conditions (detection limit ~250 pmol for all neutral aldoses). Detection with 2-cyanoacetamide has been successfully applied not only to neutral sugars but also to uronic acids, amino sugars, and the monosaccharide constituents of glycoproteins (including acetamido-deoxyhexoses and sialic acids), as well as to alditols. The fluorescent products of the reaction of 2-cyanoacetamide with reducing aldoses are believed to be 3-cyano-2-pyridone and 3-cyano-2-pyrrolidone derivatives, and there is also a product, containing a conjugated diene system in the molecular structure, which absorbs strongly at 270 nm, so that UV detection is also sensitive. As all of these products are readily oxidizable at a glassy carbon electrode, electrochemical detection is another option with this useful analytical reagent.

The specificity and sensitivity of the reagents discussed in this section are summarized in Table 2.

## Sugars – Chromatographic Methods

**S C Churms**, University of Cape Town, Rondebosch, South Africa

## Introduction

Chromatographic analysis of samples containing mixtures of sugars is an essential operation in any laboratory concerned with carbohydrates, whether

sugars as such or carbohydrates of higher molar mass (polysaccharides or glycoconjugates and their depolymerization products). Characterization of the latter requires, *inter alia*, complete degradation to the constituent monosaccharides in order to determine their nature and proportions, for which purpose chromatographic methods are crucial. Both gas chromatography (GC) and liquid chromatography (LC) are widely used in sugar analysis, but during the past decade LC has been increasingly preferred over GC. This is because derivatization prior to analysis is not usually required in LC, unless it is necessary to enhance sensitivity of detection by introduction of a chromophoric or fluorescent group. The major area of growth in chromatographic analysis of sugars in recent years has undoubtedly been in the development of what has become known as high-performance anion-exchange chromatography (HPAEC), a form of ion chromatography that is applied specifically to analysis of sugars and other carbohydrates. This is now the method of choice in many laboratories worldwide.

This article will first give an overview of the GC methods most frequently applied to sugar analysis, with emphasis on significant recent developments, such as the automation of derivatization of sugars to alditol acetates, and the potential for enhanced sensitivity in GC coupled to mass spectrometry (MS) afforded by the introduction of tandem MS (GC-MS/MS) into this field. In view of the growing preference for LC, however, the focus will be mainly on this form of chromatography, and especially HPAEC. In planar chromatography, the more rapid thin-layer chromatography (TLC) has now entirely superseded the classical technique of paper chromatography in qualitative analysis of mixtures of sugars, all the more since the widespread adoption of high-performance TLC (HPTLC) plates. A brief overview of the most effective TLC systems for this purpose, and some useful detection reagents, will be given in the final section of this article.

## Gas Chromatography

Sugars, being nonvolatile, must be converted to volatile derivatives before GC analysis is possible. During the 1970s and 1980s, many different methods of derivatization were explored, but most of the novel procedures were not pursued further. The derivatization methods that have been generally adopted as standard procedures for GC analysis of sugars of various types include conversion to acetylated alditols or aldononitriles, oximation followed by acetylation, trimethylsilylation or trifluoroacetylation,

and trimethylsilylation of the mixtures of methyl glycosides obtained on methanolysis of carbohydrates of higher molar mass. These procedures, together with some promising new techniques, are briefly discussed below.

Unless the anomeric centers of sugars are eliminated prior to GC, the chromatogram will be complicated by the production of multiple peaks. Therefore, for analysis of complex mixtures, the sugars are often reduced to the corresponding alditols by treatment with sodium borohydride (or sometimes borodeuteride). After acidification with acetic acid to destroy excess borohydride, and removal of the resulting borate by repeated evaporation with methanol, the residue is acetylated by reaction with acetic anhydride, the acetate remaining in the mixture serving as a basic catalyst. This procedure, together with the steps involved in removal of reagents and recovery of products, is relatively simple but time consuming, which is probably one of the main reasons for the shift in preference from GC to high-performance liquid chromatography (HPLC) analysis of sugars. Therefore, the recent development of a fully automated system for the preparation of alditol acetate derivatives can be considered to be an important contribution to the field. The computer-controlled instrument described by Alvin Fox and co-workers enables the multistage process to be performed sequentially without manual intervention, and also makes possible the simultaneous processing of several samples in a manifold of glass/polytetrafluoroethylene (PTFE) reaction chambers, seated in a movable heating block the temperature of which is adjusted automatically. Electrically driven solenoid valves are connected online to the sample manifold, a set of solvent valves controlling the input of solvent, reagent, and/or nitrogen gas to each chamber, and a set of gas valves controlling output to atmosphere or vacuum. Closure of all valves allows the samples to be sealed into closed chambers. Use of this apparatus permits the reduction and acetylation of samples to be performed overnight, and only the final post-derivatization cleanup (removal of excess acetic anhydride and extraction of the derivatized samples into chloroform or dichloromethane) requires manual operations. The advent of automated systems of this type, which remove the tedium from derivatization, may well lead to renewed interest in GC analysis of sugars.

An alternative method of eliminating the anomeric center in a sugar is conversion to the aldononitrile or ketoxime, and this reaction, followed by acetylation of the remaining hydroxyl groups, has also been much used as a derivatization procedure for GC analysis. The standard method, which is less time

consuming than the classical procedure for conversion of sugars to alditol acetates, involves heating the sample at 70°C with hydroxylamine hydrochloride in the presence of pyridine for 20 min, then addition of acetic anhydride and heating for a further 20 min under the same conditions. The products are extracted into chloroform for GC analysis. This derivatization method is applicable to both aldoses and ketoses; the latter are analyzed as acetylated ketoxime derivatives while, for the aldoses, the oximes formed initially are dehydrated to aldonitriles during the acetylation step. Not only neutral sugars but also aminodeoxy- and acetamidodeoxyhexoses can be derivatized in this way, but longer reaction times are required for the amino sugars. Each aldose gives a single, unique, linear derivative, but each ketose yields two products, corresponding to the geometrical isomers that differ in the configuration of the O-acetyl oxime group.

Where amino sugars are present together with neutral sugars in the mixture to be analyzed (as in hydrolysates from glycoproteins), derivatization to O-methyloximes prior to acetylation is generally preferred, as the time required for oximation is only 20–25 min for both neutral and amino sugars. In this case, the reagent used is O-methylhydroxylamine, with 1-dimethylamino-2-propanol or 4-(dimethylamino)-pyridine as a catalyst. The O-methyloxime acetates derived from the amino sugars are well separated from the neutral sugar derivatives on GC, in run times of 45 min or less. Double peaks are produced in all cases.

In recent years, trimethylsilylation has been increasingly preferred over acetylation following oximation of sugars in derivatization for GC analysis. The trimethylsilyl (TMS) oximes are more volatile, and therefore the method is applicable to sugars of all types, including acidic sugars. This GC technique has proved useful in the analysis of complex mixtures of neutral and acidic sugars (for example, those produced on hydrolysis of industrial gums) and also permits simultaneous analysis of neutral sugars, polyols, acidic sugars, and other components, such as carboxylic acids and amino acids, in natural matrices (e.g., fruit).

There has been some interest in the use of trifluoroacetylated oximes as volatile derivatives for GC analysis of sugars, as analysis can be performed at relatively low temperatures and the sensitive electron capture detector can be used. However, these derivatives are unstable in the presence of moisture, and it is therefore difficult to remove the derivatization reagent (trifluoroacetic acid anhydride); compounds other than sugars may thus be converted to halogenated derivatives, resulting in increased

background. More recently, introduction of halogen atoms by derivatization of sugars to O-pentafluorobenzyl oximes, followed by acetylation for GC analysis, has been recommended. These derivatives are stable and give highly characteristic mass spectra. They are therefore very useful in GC–MS analysis, particularly with MS in negative-ion chemical ionization mode.

Capillary GC of the TMS derivatives of the methyl glycosides and methyl glycoside methyl ethers produced on methanolysis of polysaccharides or glycoconjugates is a highly sensitive method of analysis, allowing the determination of individual components at picomolar levels. The derivatives from all the methyl glycosides in a complex mixture, including those from neutral, amino, and acidic sugars, can be separated in a single run, with relatively short analysis times. The method has thus proved particularly useful in analysis of the constituents of glycoconjugates and of acidic polysaccharides such as industrial gums. An interesting application has been the use of GC–MS of the TMS methyl glycosides from methanolysates in characterizing the plant gums and other vegetable substances present in objects of archaeological interest. Multiple peaks, corresponding to anomeric pairs and pyranose or furanose ring forms, are given by each sugar derivative, but the characteristic patterns can aid in identification, which in recent years has been greatly facilitated by the accumulation of a large body of GC–MS data for TMS methyl glycosides.

Recently, a novel method for rapid, sensitive analysis of the sugar constituents of glycoconjugates, by GC analysis of the heptafluorobutyrate derivatives of the methyl glycosides produced on methanolysis, was described by Zanetta and co-workers. Acylation with heptafluorobutyric anhydride derivatizes in a single step not only hydroxyl but also amino groups, forming products that do not interact strongly with the methyl siloxane stationary phases generally used in GC of apolar derivatives. Thus, amino sugars can be analyzed together with other sugar components within a short time. This applies also to acidic sugars, and therefore the method can be used in analysis of glycosaminoglycans.

Recommended conditions for GC analysis of the various sugar derivatives that have been discussed in this section are given in **Table 1**.

### Advances in GC–MS

GC–MS analysis of sugars has been greatly facilitated by the availability of databases containing *m/z* values and relative intensities of selected ions among those produced by the various derivatives used in

**Table 1** Conditions recommended for GC analysis of sugars

<i>Derivative</i>	<i>Column type</i>	<i>Phase</i>	<i>Temperature (°C)</i>	<i>Gas; flow rate (ml min<sup>-1</sup>)</i>
Alditols, acetylated	Packed	OV-225, 3% on Chromosorb W-HP (80-100 mesh)	210	He; 40
	Glass capillary	Silar 10C	190 (4 min); 190→230 at 4°C min <sup>-1</sup> ; 230 (8 min)	H <sub>2</sub> ; 9
	Glass capillary	SP-2340	185 (10 min); 185→220 at 3°C min <sup>-1</sup> ; 220 (5 min); 220→235 at 15°C min <sup>-1</sup> ; 235 (30 min); for separation of amino and neutral sugar derivatives	He; 5.5
	Fused-silica capillary	OV-1701 (bonded phase)	140 (0.5 min); 140→195 at 25°C min <sup>-1</sup> ; 195→250 at 6°C min <sup>-1</sup> ; 250 (8 min); for separation of amino and neutral sugar derivatives	He; 0.6
Aldononitriles and ketoximes, acetylated	Packed	OV-17, 2% on Chromosorb W-HP (80–100 mesh)	130→300 at 5°C min <sup>-1</sup>	N <sub>2</sub> ; 22
	Packed	Poly(neopentyl glycol succinate) 3% on Chromosorb W (60–80 mesh)	140→250 at 3°C min <sup>-1</sup>	N <sub>2</sub> ; 32
	Fused-silica capillary	OV-1	175 (4 min); 175→260 at 4°C min <sup>-1</sup> ; 260 (5 min); to separate amino from neutral	He; 0.5
O-Methyl oximes, acetylated	Fused-silica capillary	OV-1	As for acetylated aldononitriles; see above	He; 0.5
O-Methyl oximes, trimethylsilylated	Fused-silica capillary	SP-2100	180	He; 1
O-Pentafluorobenzyl oximes, acetylated	Fused-silica capillary	CP-Sil 88	140 (4 min); 140→240 at 10°C min <sup>-1</sup> ; 240 (10 min); separates amino from neutral	He; 3
Oximes, trimethylsilylated	Fused-silica capillary	DB-5 (bonded phase)	60 (2 min); 60→155 at 13°C min <sup>-1</sup> ; 155 (10 min); 155→250 at 13°C min <sup>-1</sup> ; 250 (12 min); to separate mono-, di-, and trisaccharides	NA
	Fused-silica capillary	DB-5	60 (2 min); 60→120 at 20°C min <sup>-1</sup> ; 120→155 at 6°C min <sup>-1</sup> ; 155 (10 min); 155→250 at 13°C min <sup>-1</sup> ; 250 (12 min); 250→330 at 20°C min <sup>-1</sup> ; 330 (10 min); to separate sugars, alditols, sugar acids, and amino acids	NA
Methyl glycosides, trimethylsilylated	Fused-silica capillary	CP-Sil 5	140 (2 min); 140→260 at 8°C min <sup>-1</sup> ; separates neutral, amino, and acidic derivatives	He; 1
	Fused-silica capillary	DB-5	150→220 at 2°C min <sup>-1</sup> ; separates neutral and acidic derivatives	N <sub>2</sub> ; 1
	Fused-silica capillary	DB-1 (bonded phase)	120→145 at 1°C min <sup>-1</sup> ; 145→180 at 0.9°C min <sup>-1</sup> ; 180→230 at 50°C min <sup>-1</sup> ; separates derivatives from all components of plant cell-wall polysaccharides, including 2-keto-3-deoxy sugars and branched sugars	H <sub>2</sub> ; 2
Heptafluorobutyrate of methanolysis products from glycoconjugates	Fused-silica capillary	CP-Sil 5 CB (low bleed)	90 (3 min); 90→260 at 5°C min <sup>-1</sup> ; 260 (10 min); separates neutral, amino, and acidic derivatives	He; 0.8 bar

NA = not available.

such analyses. A vast body of data has been collected for identification of sugars as their alditol acetate derivatives, and diagnostic MS data for characterization of the other derivatives mentioned above is now rapidly accumulating.

During the 1990s, tandem mass spectrometry attracted wide interest, and this technique is being used to an increasing extent in conjunction with GC for detection and identification of carbohydrates present in trace quantities in complex matrices (such as bacterial cell walls), an application in which optimal specificity and sensitivity are required. Both triple-quadrupole and ion-trap MS/MS have been used successfully in trace analysis of sugars (for example, muramic acid) that serve as bacterial markers in samples of environmental or clinical interest. Such sugars are usually analyzed as their alditol acetate derivatives. Quantitation is more accurate when a triple-quadrupole mass spectrometer is used, but sensitivity is higher with the ion-trap instrument. Specificity in detecting trace amounts of carbohydrate markers in complex matrices is greatest when MS/MS is used in multiple reaction monitoring mode. The sensitivity of GC–MS/MS in trace analysis of sugars is currently unmatched by that of MS/MS used in conjunction with any form of LC.

### Enantioselective GC of Sugars

Enantiomeric pairs can be resolved by capillary GC of sugar derivatives formed by reaction with chiral compounds: acetylated (+)-2-octyl glycosides and trimethylsilylated (–)-2-butyl glycosides are examples of derivatives that have been used for this purpose. In recent years, however, the focus has shifted toward the use of enantioselective stationary phases with sugar derivatives that are more readily available. König and co-workers, who are recognized as the leaders in this field, have produced very effective enantioselective stationary phases for carbohydrate analysis by modification of cyclodextrins through the introduction of hydrophobic groups. The objective of this modification has been both to lower the melting points of the cyclodextrins, to permit their use as liquid phases in GC, and to increase thermal stability. Tri-*O*-pentylated derivatives of  $\alpha$ - and  $\beta$ -cyclodextrins [hexakis(2,3,6-tri-*O*-pentyl) cyclomaltohexaose and heptakis(2,3,6-tri-*O*-pentyl) cyclomaltoheptaose] have been found to exhibit a high degree of enantioselectivity toward trifluoroacetylated derivatives of aldoses, alditols, and methyl glycosides, baseline resolution of enantiomers being achieved within 5–10 min on glass capillary columns coated with these phases (marketed as Lipodex A and C, respectively). These separations can

be achieved at relatively low column temperatures (80–120°C).

More recently, other modified cyclodextrins, such as heptakis(2,6-di-*O*-methyl-3-*O*-pentyl)cyclomaltoheptaose or octakis(2,6-di-*O*-methyl-3-*O*-pentyl)cyclomaltooctaose, have been used as stationary phases in enantioselective GC of permethylated derivatives of methyl glycosides and anhydroalditols. The acetylated derivatives of the mixture of 1,5-anhydro-*O*-methylgalactitols obtained on reductive cleavage of the permethylated galactan from a snail (*Helix pomatia*) were well resolved by capillary GC on a column coated with the modified cycloheptaose, and in this way the occurrence of terminal residues of L-galactose as well as the more usual D-galactose was clearly established. This is a striking demonstration of the potential of enantioselective GC in structural studies of polysaccharides.

## Liquid Chromatography

Of the several different modes of LC that have been developed over the years there are three that have been applied in analysis of sugars. These are: chromatography on polar stationary phases with a less polar mobile phase (formerly known as ‘normal-phase chromatography’ but now termed ‘hydrophilic interaction chromatography’, with the acronym HILIC), reversed-phase chromatography (RPC) (which generally requires precolumn derivatization of the polar sugars), and HPAEC. The use of each of these modes of chromatography in this field is briefly reviewed below.

### Hydrophilic Interaction Chromatography

This term encompasses chromatography on strongly polar, unmodified silica gel or on stationary phases bearing bonded polar groups, on a silica or a polymeric matrix. Chromatography on microparticulate silica as such can be governed by mechanisms involving either adsorption or partition, or both, while partition is generally the predominant mechanism where bonded phases are the active groups.

Unmodified silica sorbents have been used mainly in HPLC of carbohydrate derivatives, and have long been regarded as applicable to analysis of sugars only after derivatization of the analytes, since with the solvent systems generally used sugars themselves are too strongly bound to the highly polar silica to permit effective separations. The necessity for precolumn derivatization is not really a disadvantage, since the introduction of chromophoric or fluorescent groups by this means makes possible the use of detectors, such as the ultraviolet (UV) photometer or

fluorimeter, that are more sensitive than the differential refractometer generally used in HILIC of sugars. For this purpose, sugars have been derivatized to benzoates or 4-nitrobenzoates (often after reduction to the alditols to eliminate the production of multiple peaks), also to 2,4-dinitrophenylhydrazones, or fluorescent dansylhydrazones (produced by reaction with 5-dimethylaminonaphthalene-1-sulfonyl hydrazine, known as dansyl hydrazine) or pernapthoates. Of special interest is the use of reductive amination with chiral 1-( $\alpha$ -methylbenzylamine, followed by acetylation, to achieve resolution of enantiomeric pairs of aldose sugars by HPLC on silica.

In 1992, Herbreteau and co-workers reported that unmodified silica stationary phases did exhibit high selectivity for sugars and alditols if solvent systems consisting of dichloromethane–methanol mixtures, with only a trace (0.2%, v/v) of water, were used instead of the usual acetonitrile–water eluents. Good resolution of the common monosaccharides was obtained by chromatography on 5- $\mu$ m silica with such solvent systems containing 20% of methanol, while increasing the proportion of methanol to 28% permitted the separation of several disaccharides and the trisaccharide raffinose. The presence of water in only trace amounts in these solvent systems prevents the very strong binding of sugars that is exhibited by hydrated silica, allowing chromatographic separation by a partition process. Such chromatographic systems provide an attractive alternative to the use of aminopropyl silica columns (see below) for HILIC of sugars.

Of the HPLC sorbents carrying bonded polar phases, aminopropyl silica types were for many years the most widely used in analysis of sugars. However, these column packings have a short lifetime in this application, due to interaction between reducing sugars and the bonded amine groups to form glycosylamines. This reaction results not only in deactivation of the column but also losses of the sugar analytes, and is thus one of the main reasons for the widespread adoption of other forms of HPLC for sugar analysis that has been such a marked trend during the past decade.

Several alternative column packings carrying different polar bonded phases have been introduced with the objective of overcoming the problem of the instability of alkylamino groups in analyses involving reducing sugars. These include polyamine, aminocyano, and carbamoyl amide phases. However, although some successes have been achieved in HILIC of linear oligosaccharides and cyclodextrins, such stationary phases have not proved very effective in separations of monosaccharides. The most successful

for this purpose has been the hydroxylic type, in which the microparticulate silica matrix carries bonded diol groups. In the earliest applications of stationary phases of this type to the separation of sugars broad peaks were obtained, due to partial resolution of anomers, with the usual acetonitrile–water solvent systems. More recently, greatly improved resolution, with sharper peaks, was observed by Herbreteau and co-workers on replacing these solvent systems with dichloromethane–methanol systems similar to those that had proved effective in chromatography of sugars on unmodified silica. Use of the evaporative light-scattering detector under these conditions made possible gradient elution, with resulting improvements in selectivity, and the detection of the sugars at nanogram levels.

Novel stationary phases that have some advantages (especially with regard to efficiency and stability) over many of the others that have been applied to HILIC of sugars are those in which  $\alpha$ - or  $\beta$ -cyclodextrin is bonded to 5- $\mu$ m silica. Retention data published by Armstrong and Jin for a wide variety of carbohydrates, including monosaccharides from triose to heptose, deoxy sugars, di-, tri-, and tetrasaccharides, on these column packings, with eluents consisting of aqueous acetonitrile (80–85%) or acetone (85–90%) demonstrate the feasibility of separations of many such compounds that are not easily resolved by other LC methods.

Polymeric supports for HILIC are used to advantage under certain conditions where silica-based packings would be unstable; for example, at elevated column temperatures or with mobile phases containing relatively high proportions (over 20%) of water. The polymer must be in microparticulate bead form (5–10  $\mu$ m in diameter) and rigid enough to withstand high pressures and flow rates; furthermore, it should not shrink or swell to any great extent with changes of solvent.

Column packings of this type that are suitable for HILIC of sugars include highly crosslinked polystyrenesulfonate ion-exchange resins, which function as supports for partition chromatography rather than as ion-exchangers in mobile phases containing organic solvents mixed with water or buffer solutions. In this case, the separation mechanism depends on the hydrophilicity of the anionic groups on the resin and their counter-ions. For example, a resin cross-linked with 55% of divinylbenzene has been successfully used, in the hydrogen form, with an aqueous acetonitrile mobile phase to separate all the monosaccharide constituents of glycoproteins, neutral and amino sugars, in a single run. The same resin, in the sodium or calcium form, is capable of resolving the  $\alpha$ - and  $\beta$ -anomers of most of the aldopyranoses if the column is operated at low temperature (4°C).

Polymers developed specifically for HPLC include the macroporous crosslinked vinylpyridinium type, which has proved very effective in HILIC of sugars in aqueous acetonitrile. These polymers can be used at column temperatures up to 70°C, under which conditions, with the resin in the phosphate or sulfate form, baseline resolution of mixtures of the common monosaccharides and some disaccharides, such as maltose and lactose, can be achieved. Stationary phases in which a polymer replaces silica as the support for the aminopropyl bonded phase much used in HILIC of carbohydrates have also been successfully applied in separations of mono- and disaccharides; in this case precolumn derivatization with 4-amino-benzoic acid ethyl ether (ABEE) has been recommended to overcome the problem of glycosylamine formation that occurs with underivatized sugars.

### Reversed-Phase Chromatography

Chromatography on C<sub>18</sub>-bonded silica has been applied to underivatized sugars, with water as the mobile phase, but with limited success as resolution is poor and is complicated by the formation of double peaks due to anomer separation. The mechanism in this case is not really reversed-phase partition but rather a form of hydrophobic interaction chromatography. True RPC of sugars requires the introduction of nonpolar groups by precolumn derivatization. As has been mentioned, this can be advantageous in making possible the use of sensitive UV or fluorimetric detection, and the derivatives are readily identifiable by MS. Furthermore, the solvent systems used in RPC are more compatible with on-line mass spectrometry than are, for example, the acetonitrile-rich eluents generally used in HILIC. For these reasons, there has been increased use of RPC for analysis of sugars in recent years.

A highly effective method of precolumn derivatization of sugars for RPC is reductive amination, which has the effect of destroying the anomeric center, thus preventing the formation of multiple peaks, and simultaneously labeling the reducing end of each sugar with a group that is amenable to UV, fluorimetric, and MS detection. Reagents widely used for this purpose are 2-aminopyridine and, more recently, ABEE. Others that are finding application in this way include 2-aminoacridine, 8-aminonaphthalene-1,3,6-trisulfonic acid, and 2-aminobenzoic acid (anthranilic acid).

Derivatization for RPC may also be effected by introduction of chromophores through reaction with the hydroxyl groups of the sugars, but in this case multiple peaks are obtained. Nevertheless, perbenzoylation followed by RPC has been used as an

alternative to GC of the trimethylsilylated product for the analysis of methanolysates from polysaccharides and glycoconjugates. With microbore RPC columns, analysis of the benzoylated methyl glycosides is possible at the picomolar level. RPC has also proved effective in analysis of acetylated carbohydrates: for example, the method can be used instead of GC in analysis of sugars as the peracetylated aldono-nitrile or ketoxime derivatives.

As in the case of HILIC, the use of polymeric supports for RPC can be advantageous. A vinyl alcohol co-polymer carrying bonded C<sub>18</sub> chains has been successfully used in chromatography of sugars and oligosaccharides in aqueous media, the formation of double peaks due to anomerization being prevented by addition of sodium hydroxide to the mobile phase (to pH 11). Silica-based supports are not stable under such conditions.

An important development during the past decade has been the introduction of graphitized carbon stationary phases for HPLC of underivatized carbohydrates. Monosaccharides are weakly retained on these columns and, in the aqueous mobile phases used to separate these sugars from oligosaccharides, double peaks are produced on chromatography. However, this system gives sharp resolution of disaccharides if sodium hydroxide is added to the eluent: for example, nine gluco-disaccharides have been resolved in 25 min on a graphitized carbon column by use of an acetonitrile gradient (1.5–5.0%) in dilute sodium hydroxide (1 mmol l<sup>-1</sup>).

### High-Performance Anion-Exchange Chromatography

Neutral sugars, being very weak electrolytes with pK<sub>a</sub> values of the order of 12–13, do not interact with anion-exchangers to any appreciable extent in neutral aqueous media. They can be converted to anionic complexes in the presence of borate, which then permits analysis by anion-exchange chromatography on a microparticulate resin. This was formerly a widely used technique in sugar analysis. However, run times are long and have remained so (up to 6 h) despite the introduction of more efficient resin columns during the 1980s. Therefore, ion-exchange chromatography of sugars is now performed almost exclusively at high pH, under which conditions the hydroxyl groups on the sugars are dissociated, so that the sugars become anionic.

Chromatography of sugars at high pH presents some problems, which had to be overcome before the use of this technique became feasible. First, carbohydrates are susceptible to base-catalyzed reactions, such as isomerization of reducing sugars or degradation

of oligosaccharides by  $\beta$ -elimination, on prolonged exposure to strong alkali. For this reason, chromatographic supports that are capable of faster interaction than the usual silica or polymeric types are required, to enable separations to be finished rapidly enough to minimize these structural changes during chromatography. High efficiency is also necessary, as the carbohydrate anions are weakly retained in comparison with the common inorganic anions. In 1983, the Dionex Corporation (Sunnyvale, CA, USA) introduced stationary phases that had been developed for this specific purpose: these are pellicular supports consisting of nonporous latex beads, of particle diameter 5 or 10  $\mu\text{m}$ , coated with a thin film of strongly basic anion-exchanger (now marketed under the trade name CarboPac).

The second problem was that the detectors generally used in HPLC were not suited to the conditions to be employed here. This was overcome by the simultaneous development of the pulsed amperometric detector (PAD). The carbohydrates eluted from the column are oxidized at the surface of a gold electrode, a selected potential being applied between this and a silver/silver chloride reference electrode. Pulsed-potential operation is necessary to avoid rapid deactivation of the electrode surface due to adsorption of intermediates produced during carbohydrate oxidation. The potential required for oxidation of the analytes is applied to the working electrode for a very short time (100 ms or less), and then it is increased to oxidize fully any material adsorbed on the electrode surface, after which it is reversed to a strongly reducing potential to convert the oxide layer back to the metal. These detectors require highly alkaline conditions for their operation, and are thus ideal for use in chromatography of carbohydrates at high pH. The sensitivity of the detector can be varied over a wide range, as can the pulse width. Detection of carbohydrates at picomolar levels is possible.

The technique of HPAEC–PAD has now become indispensable in the analysis of sugars and other carbohydrates. The power of the method lies in its superior efficiency, high sensitivity, and simplicity of sample handling (derivatization is not required). It is applicable not only to sugars but also to carbohydrates of relatively high molar mass, including the complex oligosaccharides released on degradation of glycoconjugates.

For analysis of monosaccharides the eluent that has been most widely used is NaOH (150–160  $\text{mmol l}^{-1}$ ), although various modifications have been introduced for specific purposes. For example, xylose and mannose, which occur together in hydrolysates from glycoconjugates of plant origin,

coelute under these conditions, and therefore the use of a more dilute alkaline eluent (1  $\text{mmol l}^{-1}$  NaOH) containing sodium acetate (0.03  $\text{mmol l}^{-1}$ ) has been recommended for analysis of such samples. With this solvent system and others containing the strong alkali at low concentrations postcolumn addition of NaOH is necessary for effective functioning of the PAD. This applies in particular to analyses involving amino sugars, which are best resolved with eluents containing 10–15  $\text{mmol l}^{-1}$  NaOH, but are detected satisfactorily only after addition of 0.3  $\text{mol l}^{-1}$  NaOH to the column effluent.

It has been shown that the presence in the mobile phase of monovalent ions other than  $\text{Na}^+$  does not significantly change the selectivity of the HPAEC system for sugars. However, recent studies have demonstrated that the introduction of alkaline earth cations in small proportion (1–2  $\text{mmol l}^{-1}$ ) into dilute alkaline eluents (5–20  $\text{mmol l}^{-1}$  NaOH) results in sharper peaks and improves resolution, especially in analysis of mixtures of monosaccharides and alditols.  $\text{Ba}^{2+}$  and  $\text{Sr}^{2+}$  ions appear to be more effective in this respect than  $\text{Ca}^{2+}$ . For example, with an eluent consisting of dilute NaOH (5  $\text{mmol l}^{-1}$ ) containing 1  $\text{mmol l}^{-1}$  barium acetate, a mixture of alditols and sugars, the former eluting earlier than the latter, can be completely resolved on the standard CarboPac PA-1 column (Dionex) within 15 min. Use of a higher concentration of alkali (20  $\text{mmol l}^{-1}$  NaOH) with the same concentration of barium acetate permits sharp resolution of the mixtures of neutral and amino sugars in hydrolysates from glycoconjugates, also in a short run time (less than 12 min). The presence of  $\text{Ba}^{2+}$  or  $\text{Sr}^{2+}$  ions in the mobile phase has also been shown to increase PAD response, for neutral, amino, and acidic sugars. These effects of alkaline earth cations have been ascribed to the formation of soluble complexes between these cations and sugars or alditols, as well as removal from the eluent of carbonate ions formed by dissolution of atmospheric  $\text{CO}_2$ .

The presence of acetate ions in the mobile phase can also be advantageous in HPAEC, especially in analysis of oligosaccharides, which are eluted earlier under such conditions. These anions have a slightly higher affinity for the strongly basic anion-exchange groups on the stationary phase than have  $\text{OH}^-$  ions, and therefore strongly bound solutes, such as oligosaccharides (including those of high degree of polymerization) and acidic saccharides, are more easily displaced in the presence of acetate. The use of an acetate gradient has proved very effective in such analyses (see Table 2).

The PAD has remained the most frequently used detector for HPAEC, but other methods are occasionally

**Table 2** Conditions recommended for LC analysis of sugars

Stationary phase	Mobile phase	Derivatization	Temperature <sup>a</sup> (°C)	Detection <sup>b</sup>
Unmodified silica	Dichloromethane–methanol–water (80:19.8:0.2)	None	RT	RI or evaporative light-scattering
	Dichloromethane–methanol–water (72:27.8:0.2); separates mono-, di-, and some trisaccharides	None	RT	As above
	<i>n</i> -Hexane–dioxane–dichloromethane, linear gradient, 22:2:1 → 4:2:1 (80 min)	As benzoylated alditols	RT	UV (275 nm)
	<i>n</i> -Hexane–chloroform–acetonitrile (5:2:1)	As 4-nitrobenzoyl alditols	RT	UV (260 nm)
	Chloroform–methanol–water (91.7:7.6:0.7)	As 2,4-dinitro-phenylhydrazones	RT	UV (352 nm)
	Chloroform–ethanol–water, 86:12:2 (4 min); 78:19.5:2.5 (20 min)	As dansylhydrazones	27	Fluorimetry (excitation 350 nm, emission 500 nm)
	(A) 2-Propanol (0.025%) in dichloromethane; (B) Acetonitrile (4%) in A; A + B, 85:15 (15 min); 85:15 → 20:80 (15 min); 20:80 (10 min)	As pernapthoates of derived alditols	RT	Fluorimetry (excitation 234 nm, emission 374 nm)
	<i>n</i> -Hexane–ethanol (19:1)	As 1-( <i>N</i> -acetyl- $\alpha$ -methylbenzyl-amino)-1-deoxy-alditol acetates; enantiomers resolved	RT	UV (230 nm)
Aminopropyl silica	Acetonitrile–water (4:1 for monosaccharides, 3:1 for di- and trisaccharides)	None	RT	RI
Diol-bonded silica	Dichloromethane–methanol (84:16)	None	RT	RI or evaporative light-scattering
$\alpha$ -Cyclodextrin bonded to silica	Acetonitrile–water (4:1) or acetone–water (17:3)	None	RT	RI
$\beta$ -Cyclodextrin bonded to silica	Acetonitrile–water (17:3) or acetone–water (9:1)	None	RT	RI
Polystyrenesulfonate cation-exchange resin, 55% DVB, H <sup>+</sup> -form	Acetonitrile–water (23:2); separates neutral and amino sugars in glycoprotein hydrolysates	None	30	Postcolumn reaction with 2-cyanoacetamide; UV (280 nm)
Resin as above, Na <sup>+</sup> - or Ca <sup>2+</sup> -form; to resolve anomeric pairs	Acetonitrile–water (4:1)	None	4	As above
<i>N</i> -Methyl-4-vinyl-pyridinium polymer, phosphate form	Acetonitrile–water (4:1); separates mono- and disaccharides	None	70	RI
Amine-bonded vinyl alcohol copolymer	Acetonitrile–water (9:1 for monosaccharides, 85:15 for disaccharides)	Reductive amination with ABEE	25	UV (304 nm)
C <sub>18</sub> -silica	Acetonitrile–water, linear gradient, 35 → 90% acetonitrile (65 min); 90% acetonitrile (10 min)	As benzoylated methyl glycosides	RT	UV (230 nm)
	Water–tetrahydrofuran–methanol (13:2:5) or methanol–water, linear gradient, 40 → 5% methanol (10 min)	As peracetylated aldonitriles and ketoximes	RT	UV (195, 207, and 215 nm)
	Acetic acid (80 mmol l <sup>-1</sup> )–acetonitrile (79:21 for monosaccharides, 76:24 for mixtures of mono- and disaccharides)	As dansylhydrazones	RT	Fluorimetry (excitation 370 nm, emission 540 nm)

Table 2 Continued

Stationary phase	Mobile phase	Derivatization	Temperature <sup>a</sup> (°C)	Detection <sup>b</sup>
Pellicular anion-exchanger (CarboPac PA-1)	Sodium citrate buffer (0.25 mol l <sup>-1</sup> , pH 4.0) containing acetonitrile (1.0%)	Reductive amination with 2-amino-pyridine	25	Fluorimetry (excitation 320 nm, emission 400 nm)
	(A) Sodium acetate buffer (50 mmol l <sup>-1</sup> , pH 4.5); (B) Solvent A–acetonitrile– methanol (2:2:1); A and B mixed 3:1	Reductive amination with ABEE	45	UV (254 and 304 nm)
	(A) 1-Butylamine (0.2–0.3%), H <sub>3</sub> PO <sub>4</sub> (0.5%) and tetrahydrofuran (1%) in water; (B) Solvent A–acetonitrile (1:1); A + B (95:5) for 25 min; 5 → 15% B (50 min)	Reductive amination with anthranilic acid	RT	Fluorimetry (excitation 230 nm, emission 425 nm)
	NaOH, 150–160 mmol l <sup>-1</sup> for most neutral sugars, 10– 15 mmol l <sup>-1</sup> for amino sugars	None	RT	Pulsed amperometric detector (PAD)
	NaOH, 5 mol l <sup>-1</sup> , containing barium acetate, 1 mmol l <sup>-1</sup> ; separates alditols from sugars	None	RT	PAD
	NaOH, 20 mmol l <sup>-1</sup> , containing barium acetate, 1 mol l <sup>-1</sup> ; separates neutral from amino sugars	None	RT	PAD
	NaOH, 15 mmol l <sup>-1</sup> (15 min); linear gradient, 15 → 100 mmol l <sup>-1</sup> NaOH, 0 → 150 mmol l <sup>-1</sup> sodium acetate (40 min); separates acidic sugars from neutral and amino	None	RT	PAD

<sup>a</sup> RT = room temperature.<sup>b</sup> RI = refractive index detector; UV = ultraviolet.

employed where sugars are present in trace amounts in complex biological samples such as cell lysates. In this case, radiochemical labeling or derivatization with fluorogenic reagents is used to increase the sensitivity of detection. Direct coupling of HPAEC to MS presents problems due to the high salt content of the mobile phases; however, recent improvements in desalting methods (for example, the use of micro-membrane suppressors or online microdialysis) are rapidly overcoming these difficulties. Since matrix-assisted laser desorption/ionization/time-of-flight mass spectrometry shares with HPAEC the capability of analyzing carbohydrates in their native forms with high efficiency and sensitivity, there has been an increasing tendency to combine the two techniques in seeking to optimize such analyses. Coupling of HPAEC systems to electrospray ionization MS is also becoming more successful with the development of online desalting systems, with disaccharides such as sucrose, maltose, and trehalose now detectable at picogram levels.

Some recommended conditions for analysis of sugars by HPAEC and the other LC systems discussed in this section are given in Table 2.

### Thin-Layer Chromatography

Although TLC on cellulose plates is effective in separating mixtures of sugars, including amino and acidic sugars, multiple development or two-dimensional TLC with different solvent systems is usually required, and the method is seldom used today. TLC on unmodified silica gel plates is suitable only for carbohydrate derivatives of low polarity, such as methyl ethers, as polar sugars are too strongly adsorbed by the highly polar stationary phase (see also section on Liquid Chromatography). Prior impregnation of the silica gel layer with an inorganic salt that interacts with carbohydrates is necessary for effective TLC of mixtures of closely related sugars and alditols. Borate or phosphate buffers have been widely

used for this purpose. Inclusion of boric acid or lactic acid in the solvent system has also proved effective. A recent study has shown that both the cation and the anion of the impregnating salt can influence the selectivity of silica gel plates for sugars; for example, transition metal cations have a greater effect than alkali metals.

The introduction of HPTLC plates, coated with silica gel of small particle size, in thinner, denser, and more uniform layers than those on conventional TLC plates, has resulted in vast improvements in efficiency and resolution for TLC of sugars. Separations of analytes in nanogram and picogram amounts are possible with sensitive detection, and run times have been reduced (often to less than 10 min). As in the case of conventional TLC impregnation of the plates with phosphate or borate buffers or addition of boric acid to the solvent system is usually necessary to improve resolution. With HPTLC plates carrying a bonded aminopropyl phase, which tends to react covalently with the hydroxyl groups of the sugars, prior impregnation of the plate with sodium dihydrogen phosphate is essential to prevent such interaction.

Some TLC systems that have proved effective in separations of sugars are listed in Table 3.

### Detection Reagents for TLC of Sugars

The chromogenic spray reagents used to visualize sugars on TLC plates can be classified into four main types, according to the kind of reaction responsible for color formation:

1. Reduction by sugars.
2. Reaction of the sugars with an acid to produce 2-furaldehyde (furfural) derivatives, which then condense with phenols or aromatic amines.
3. Glycol cleavage with periodic acid or sodium metaperiodate, followed by reaction of the products to yield visible or fluorescent spots.
4. Reactions involving specific structural features, such as keto, amino, or carboxylic acid groups.

Detection limits with such visualization reagents are generally at microgram levels. Greater sensitivity is possible by use of reagents that are fluorogenic or produce a UV-absorbing chromophore in derivatizing sugars. Detection at nanogram levels is possible when fluorimetry or techniques such as UV diffuse-reflectance densitometry are used in scanning the plates. As in LC prederivatization of sugars is sometimes advantageous in TLC. The most successful reagent for this purpose has been dansyl hydrazine, which gives intensely fluorescent products with

**Table 3** TLC systems useful in separation of sugars

<i>Stationary phase</i>	<i>Mobile phase<sup>a</sup></i>	<i>Special features</i>
Silica gel 60	2-Butanone–acetic acid–saturated aqueous solution of boric acid (9:1:1)	Good resolution of monosaccharides
	2-Propanol–acetone–1 mol l <sup>-1</sup> lactic acid (2:2:1)	Separates mono-, di-, and trisaccharides
	2-Butanone–2-propanol–acetonitrile–0.5 mol l <sup>-1</sup> boric acid + 0.25 mol l <sup>-1</sup> 2-propylamine (4:3:1:2)	Separates mono-, di-, and trisaccharides
Silica gel 60, impregnated with boric acid (30 mmol l <sup>-1</sup> )	1-Butanol–ethyl acetate–2-propanol–water (35:10:6:3)	Good resolution of aldoses and ketoses
Silica gel 60, impregnated with	Acetone–water (9:1)	Separates mono-, di-, and trisaccharides
NaH <sub>2</sub> PO <sub>4</sub> (0.2 mol l <sup>-1</sup> )	1-Butanol–2-propanol–water (3:5:2)	Separates mono- and disaccharides
NaH <sub>2</sub> PO <sub>4</sub> (0.3 mol l <sup>-1</sup> )	Acetone–1-butanol–water (8:1:1)	Good resolution of aldoses and ketoses
NaH <sub>2</sub> PO <sub>4</sub> (0.5 mol l <sup>-1</sup> )	2-Propanol–acetone–0.1 mol l <sup>-1</sup> lactic acid (2:2:1)	Separates mono-, di-, and trisaccharides
Silica gel 60, HPTLC plates	2-Propanol–1-butanol–80 mmol l <sup>-1</sup> boric acid (5:3:1)	Separates alditols and monosaccharides
	Ethyl acetate–pyridine–water–acetic acid–propionic acid (10:10:2:1:1)	Separates mono-, di-, and trisaccharides
Silica gel 60, HPTLC plates, impregnated with phosphate buffer, pH 8.0	2-Butanone–acetic acid–80 mmol l <sup>-1</sup> boric acid (9:1:1)	Good resolution of pentoses
Aminopropyl silica, HPTLC plates	Acetonitrile–water (7:3)	Separates di-, tri-, and tetrasaccharides; aldoses react with amino groups
As above, impregnated with NaH <sub>2</sub> PO <sub>4</sub> (0.2 mol l <sup>-1</sup> )	Acetonitrile–water (7:3)	Separates mono-, di-, tri-, and tetrasaccharides

<sup>a</sup>All proportions are by volume.

**Table 4** Detection reagents for TLC of sugars

<i>Reagent</i>	<i>Procedure after spraying</i>	<i>Color produced</i>	<i>Detection limits</i>
<b>Chromogenic reagents</b>			
Aniline phosphate: aniline ( $2 \text{ mol l}^{-1}$ ) in water-saturated 1-butanol, mixed 1:2 (v/v) with $\text{H}_3\text{PO}_4$ ( $0.67 \text{ mol l}^{-1}$ ) in 1-butanol	Heated at $105^\circ\text{C}$ for 10 min	Aldopentoses – red-brown; aldohexoses – yellow-brown; sorbose – yellow-brown; other ketoses react only at high concentration	2–4 $\mu\text{g}$ for most aldoses
Aniline phthalate: aniline hydrogen phthalate (0.93%, m/v) mixed with phthalic acid (1.66%, m/v) in water-saturated 1-butanol	Heated at $105\text{--}120^\circ\text{C}$ for 5 min	Aldopentoses – red; aldohexoses, deoxy, and amino sugars – brown; uronic acids – orange-brown; very weak reaction with ketoses	1–2 $\mu\text{g}$ for most aldoses
Diphenylamine–aniline–phosphoric acid: diphenylamine (2%, m/v) and aniline (2%, v/v) mixed 10:1 (v/v) with 85% aqueous $\text{H}_3\text{PO}_4$	Air-dried, then heated at $100^\circ\text{C}$ for 10 min	Aldopentoses – olive green; aldohexoses – blue-grey; deoxypentoses – pink to violet; deoxyhexoses – yellow to green; ketoses – yellow to red; for disaccharides colors depend on both composition and linkage	Monosaccharides 1–5 $\mu\text{g}$ ; disaccharides 5–10 $\mu\text{g}$
1-Naphthol–phosphoric acid: 1-naphthol (1-hydroxynaphthalene) (0.5%, m/v) in aqueous ethanol (50%, v/v), mixed 10:1 (v/v) with $\text{H}_3\text{PO}_4$	Heated at $90^\circ\text{C}$ for 10–15 min	Aldopentoses – purple; deoxy sugars – orange; pentuloses – blue; other ketoses – violet	Aldopentoses and 6-deoxyhexoses 0.5 $\mu\text{g}$ ; 2-deoxyhexoses 2 $\mu\text{g}$ ; ribulose 0.5 $\mu\text{g}$ ; other ketoses 1–2 $\mu\text{g}$
Naphthoresorcinol: naphthoresorcinol (1,3-dihydroxynaphthalene) (0.2%, m/v) in ethanol, mixed 25:1 (v/v) with $\text{H}_2\text{SO}_4$	Heated at $105^\circ\text{C}$ for 5 min	Xylose – brown; other aldopentoses – light blue; aldohexoses – blue to violet; 2-deoxyribose – green; 2-deoxyhexoses – light blue; 6-deoxyhexoses – pink; ribulose – green; xylulose – orange; other ketoses – purple-red; uronic acids – blue	Aldopentoses 1–2 $\mu\text{g}$ ; aldohexoses 2–4 $\mu\text{g}$ ; deoxy sugars 0.5 $\mu\text{g}$ ; ribulose 0.5 $\mu\text{g}$ ; xylulose 0.2 $\mu\text{g}$ ; hexuloses 0.1–0.5 $\mu\text{g}$ ; heptuloses 0.5–4 $\mu\text{g}$ ; uronic acids 1–5 $\mu\text{g}$
Periodate–permanganate: aqueous solution of $\text{NaIO}_4$ (2%, m/v) mixed 2:1 (v/v) with solution of $\text{KMnO}_4$ (1%, m/v) in aqueous $\text{Na}_2\text{CO}_3$ (2%, m/v)	Air-dried	Yellow spots produced by most sugars after 20–30 min	Aldopentoses 4 $\mu\text{g}$ ; other aldoses 1–2 $\mu\text{g}$
Triphenyltetrazolium chloride: 2,3,5-triphenyltetrazolium chloride (4%, m/v) in methanol, mixed 1:1 (v/v) with $\text{NaOH}$ ( $1 \text{ mol l}^{-1}$ ) in methanol	Heated at $100^\circ\text{C}$ for 5–10 min	Reducing sugars give pink to red spots	1 $\mu\text{g}$ for most reducing sugars
<b>Specific reagents</b>			
<b>For amino sugars</b>			
Ninhydrin: ninhydrin (0.1%, m/v) in 1-butanol	Heated at $105\text{--}110^\circ\text{C}$ for 10 min	Amino sugars and amino acids give purple spots; better distinguished in presence of cupric ions (see below)	0.5 $\mu\text{g}$
Ninhydrin–Cu(II): (A) ninhydrin (2%, m/v) in ethanol; acetic acid (20%, v/v) and collidine (4%, v/v) added; (B) $\text{Cu}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$ (1%, m/v) in ethanol; A and B are mixed 50:3 (v/v) just before use	Heated at $105^\circ\text{C}$ for 2–3 min	Aminodeoxyhexoses – intense yellow-brown spots; aminodideoxyhexoses (e.g. fucosamine) – orange-yellow; amino acids – grey, red, or purple	0.1–0.2 $\mu\text{g}$ for most amino sugars

Continued

Table 4 Continued

Reagent	Procedure after spraying	Color produced	Detection limits
For 6-deoxyhexoses Sulfosalicylic acid: sulfosalicylic acid (2%, m/v) in H <sub>2</sub> SO <sub>4</sub> (0.5 mol l <sup>-1</sup> )	Heated at 110°C for 15 min	6-Deoxyhexoses – yellow; all other sugars – gray to gray- brown	Rhamnose 0.3 µg; fucose 0.5 µg; other sugars 1–2 µg
For ketoses 2,4-Dinitrophenyl- hydrazine: 2,4-dinitro- phenylhydrazine (0.4%, m/v) in HCl (2 mol l <sup>-1</sup> )	Heated at 105°C for 5 min	Ketoses or ketals – orange	1–2 µg for most keto compounds
Resorcinol–hydrochloric acid: resorcinol (0.2%, m/v) in 1-butanol, mixed 1:1 (v/v) with HCl (0.25 mol l <sup>-1</sup> ) just before use	Heated at 105°C for 5 min	Pentuloses – blue; hexuloses – red	1–2 µg for most ketoses
Thiobarbituric acid– H <sub>3</sub> PO <sub>4</sub> : thiobarbituric acid (0.5%, m/v) in ethanol, mixed 50:1 (v/v) with H <sub>3</sub> PO <sub>4</sub> (85%)	Heated at 100°C for 10 min	Ketoses and oligosaccharides containing ketoses – yellow to orange	Pentuloses 4 µg; hexuloses 0.5 µg; heptuloses 0.5–2 µg
Urea–sulfuric acid: urea (25%, m/v) in H <sub>2</sub> SO <sub>4</sub> (2 mol l <sup>-1</sup> ), mixed 1:5 (v/v) with ethanol	Heated at 100°C for 20–30 min	Hexuloses – blue; other ketoses – yellow-brown	Pentuloses and hexuloses 0.5 µg; heptuloses 1 µg
For uronic acids Mixed indicators: thymol blue (0.005%, m/v), methyl red (0.025%, m/v), and bromothymol blue (0.06%, m/v) in ethanol (95%); pH adjusted with NaOH (1 mol l <sup>-1</sup> ) until blue-green color reached	Observed at room temperature	Uronic acids and oligomers (e.g. oligogalacturonic acids) give red spots on dark green background	About 5–10 µg
<i>Fluorogenic reagents</i>			
Fluorescamine: (A) triethylamine (10%, v/v) in dichloromethane; (B) fluorescamine (4-phenyl- spiro[furan-2-(3H),1'- phthalan]-3,3'-dione) (0.05%, m/v) in acetone	Plate sprayed with A, air- dried, sprayed with B, air-dried, then sprayed again with A; spraying with base is necessary to stabilize and intensify fluorescence	Specific for amino- and acetamidodeoxy sugars; fluorimetric scanning (excitation 390 nm, emission 475 nm)	50–100 pmol
Lead tetraacetate–2,7- dichlorofluorescein: (A) lead tetraacetate (saturated solution) in glacial acetic acid; (B) 2,7- dichlorofluorescein in water (1%, m/v, or lower, down to 0.2%, if back- ground interferes with detection); A and B are mixed 1:1 (v/v), then toluene (19:1, v/v) is added	Plate is dipped in reagent for ~10 s, then heated at 100°C for 3 min	All carbohydrates with vicinal diol groups, oxidized by lead tetraacetate, are detected; fluorimetric scanning (excitation 313 nm, emission 366 nm)	50–100 pmol
Malonamide: malonamide (1%, m/v) in sodium carbonate buffer (1 mol l <sup>-1</sup> , pH 9.2)	Heated at 120°C for 20 min	Fluorimetric scanning (excitation 328–382 nm, emission 383– 425 nm)	0.25 nmol for most reducing sugars; deoxyhexoses 0.5 nmol

reducing aldoses, and the corresponding chloride, which reacts only with amino compounds (including amino sugars).

Some useful chromogenic and fluorogenic reagents for detection of sugars in TLC are listed in Table 4.

## Introduction

Sugars and sugar alcohols are one of the most abundant classes of organic molecules in various

environments and have biologically significant roles. Recent advances in biochemistry have stimulated the demand for the analytical determination of these compounds. In addition, these molecules are widespread in food and beverages; hence, their determination can be considered an important step because sugars and alditols contribute to the nutritional value, flavor, and organoleptic characteristics of foods. The development of high-performance liquid chromatography (HPLC) techniques, based on

reducing aldoses, and the corresponding chloride, which reacts only with amino compounds (including amino sugars).

Some useful chromogenic and fluorogenic reagents for detection of sugars in TLC are listed in Table 4.

## Sugar Alcohols

## Introduction

Sugars and sugar alcohols are one of the most abundant classes of organic molecules in various

environments and have biologically significant roles. Recent advances in biochemistry have stimulated the demand for the analytical determination of these compounds. In addition, these molecules are widespread in food and beverages; hence, their determination can be considered an important step because sugars and alditols contribute to the nutritional value, flavor, and organoleptic characteristics of foods. The development of high-performance liquid chromatography (HPLC) techniques, based on

hydrophilic interactions, size exclusion, or ion exclusion, has provided effective methods for separating sugar alcohols. Very recently, capillary electrophoresis (CE) has also emerged as a powerful separation tool in these analyses. A major problem with carbohydrate detection in liquid chromatography (LC) or CE is that this class of molecules, which frequently lack chromophores or fluorophores, limits the use of ultraviolet (UV) and fluorescence detectors, unless these molecules were previously derivatized. The most popular detectors are the differential refractive index and evaporative light scattering detectors, both of which have poor detection limits. Also reported is the use of preadditives in the background electrolyte (BGE) in CE for on-column derivatization, which convert these molecules in high-absorbing moieties. On the other hand, direct electrochemical detection without a prior derivatization procedure has gained prominence. For identification, LC-mass spectrometry (MS) and CE-MS are preferred.

## Types of Compounds and Matrices

Sugar alcohols are sugar derivatives in which the aldo or keto group has been reduced to the corresponding hydroxyl group. Polyols are usually classified into two different groups: (1) glycitols, or acyclic polyols, consisting of linear chains of three to seven carbon atoms (or more when they are branched), and (2) cyclitols, or cyclic polyols, such as inositol and inositol derivatives.

The most common acyclic polyols are shown in **Figure 1**. If the various possible branch-chained, methylated, and longer-chain polyols are considered, the number of possible sugar alcohols increases enormously. Some of these compounds are found in nature, such as D-volemitol, D-glycero-D-manno-D-thaloheptitol, and D-perseitol. They are widespread in the animal and plant kingdoms as free compounds or forms conjugated to lipids, polysaccharides, and plant growth regulators. Bacteria also produce a large number of acyclic polyols, some of them related to phosphorylation-dephosphorylation mechanisms of hexose transport through plasmalemma.

Inositols are cyclohexanehexols that naturally occur as free, methylated, or phosphorylated forms. Of the nine possible isomers (**Figure 2A**), three are synthetic (*epi*-, *allo*-, and *cis*-inositol), seven are optically inactive as *meso* forms, and two are enantiomorphs (D- and L-*chiro* inositol). However, phosphorylation or methylation of the inositol isomer most widely distributed in the nature, *myo*-inositol, at one of the hydroxyl groups 1, 3, 4, or 6 lead to chiral compounds, as shown in **Figure 2B**. Inositol

methylethers are found only in plants whereas *scyllo*-inositol also occurs in animals, presumably derived from plant foods.

Phosphorylated inositols are the most important form of cyclitols in plant and animal metabolisms. Phosphate residues can individually be bound to hydroxyl groups of the inositol as a phosphomonoester, forming an inositol-(poly)-orthophosphate (see **Figure 3**). Alternatively, a phosphate residue can esterify two neighboring hydroxyl groups to form a phosphodiester. Orthophosphate can be replaced by pyrophosphate (diphosphate) in a linearly or cyclically linked ester or diester, respectively, although phosphodiesters of inositol rarely occur. Depending on the number of phosphate residues, inositol phosphates are called as mono-, bis-, tris-, tetrakis-, pentakis-, or hexakisphosphate.

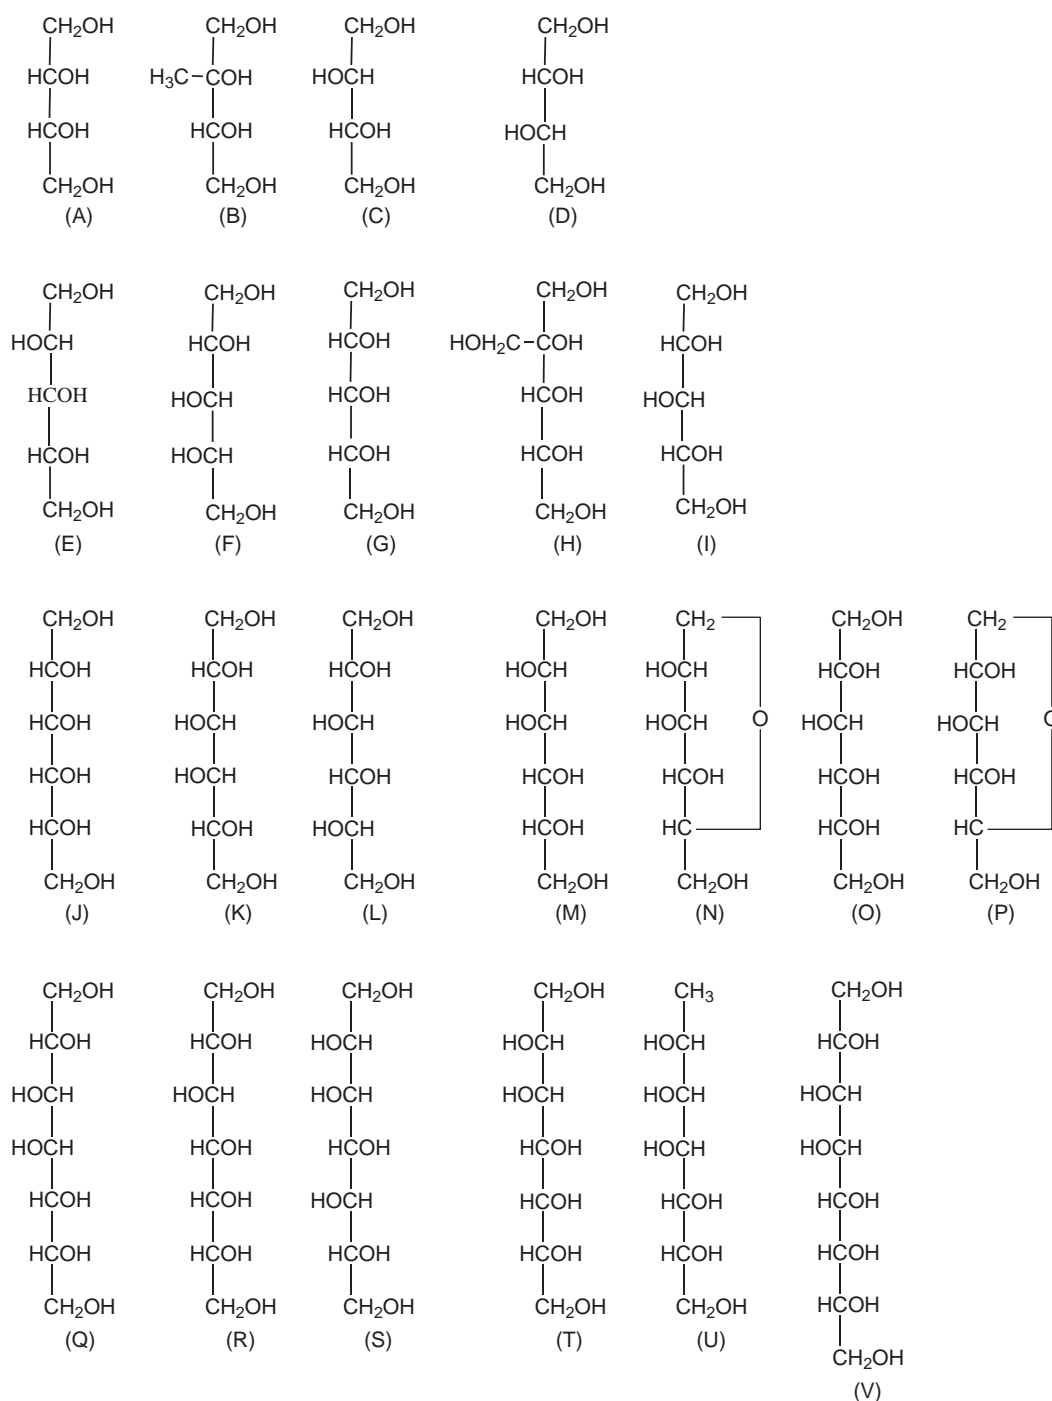

## Special Considerations in Sample Handling and Storage of Samples

Sugar alcohols should be extracted immediately from fresh material to avoid their enzymatic degradation. Air-dried plant material and even material stored at deep freeze temperatures ( $-25^{\circ}\text{C}$ ) over a long period should be avoided for the same reason. Plant material must be free of microbial infection and contamination.

Fractionation of the material is recommended because certain substances interfere with some detection methods. Percolation with petroleum ether removes lipophilic substances. Proteins and mucilages can be removed by precipitation with metal ions or 5% (w/v) trichloroacetic acid (TCA). Discoloration of biological materials is achieved with charcoal. Owing to the insolubility of benzyldine derivatives of sugar alcohols in water, they can easily be crystallized and purified from adhering matter by washing with water.

Human plasma and cerebrospinal fluid (CSF) samples must be frozen immediately after they are collected, and must be stored at  $-70^{\circ}\text{C}$  until analyzed. For plasma and CSF, borosilicate glass test tubes must be silanized with 5% (w/v) trimethylchlorosilane in hexane for 30 min at  $75^{\circ}\text{C}$  and unreacted reagent is removed by rinsing with methanol.

Glucose, sucrose, and polyhydric alcohols, glycerol, sorbitol, and mannitol, display nucleophilic reactivity with simple activated esters in aqueous solution buffered at neutral to alkaline pH. This nucleophilic reactivity is attributed to the anion resulting from ionization of a hydroxyl group. These polyhydric alcohols have been shown to be catalytically active in the hydrolysis of cephalosporins in

**Figure 1** Structural formulas of acyclic polyols: A = *meso*-erythritol; B = 2-C-methylerythritol; C = D-Threitol; D = L-threitol; E = D-aribitol; F = L-arabitol; G = *meso*-ribitol; H = D-hamamelitol; I = *meso*-xylitol; J = *meso*-allitol; K = *meso*-galactitol; L = L-Iditol; M = D-mannitol; N = 1,5-anhydro-D-mannitol; O = D-glucitol; P = 1,5-anhydro-D-glucitol; Q = D-glycero-D-galacto-heptitol; R = D-glycero-D-glucoheptitol; S = D-glycero-L-guloheptitol; T = D-glycerol-D-mannoheptitol; U = 7-deoxy-D-glycero-D-mannoheptitol; V = D-erythro-D-galacto-octitol.

aqueous solution. The reaction mechanism involves opening of the  $\beta$ -lactam moiety by an alkoxide ion derived from proton ionization of one of the hydroxyl groups generating an intermediate ester which undergoes further hydrolysis.

Glucose may interfere with sorbitol and galactitol estimation by gas-liquid chromatography (GLC) and therefore it must be removed prior to analysis by incubating samples with glucose oxidase. It is also recommended that monosaccharides be

**Figure 2** Structural formulas of cyclitols and the appearance of chiral forms after methylation or phosphorylation.

converted to the corresponding methyloxime derivatives prior to acetylation in order to avoid interferences in galactitol and mannitol estimation when using GLC as separation method. When GLC is chosen as analytical procedure, pyridine

tends to mask polyol peaks with short retention time values. In such cases, the reacted sample may be dried down and redissolved in a more volatile solvent such as chloroform, hexane, or heptane.

**Figure 3** Chromatogram in GC of a standard solution of ten sugar alcohols. Peaks are: s=solvent front; 1=erythritol; 2=pentaerythritol; 3=ribitol; 4=arabitol; 5=xylitol; 6=mannitol; 7=galactitol; 8=sorbitol; 9=inositol; 10=perseitol. The retention time of pentaerythritol was 4 min.

## Methods of Determination

### Extraction Procedures

Extraction of sugar alcohols is usually performed with boiling ethanol containing different percentages in water (e.g., 70%, 80%, 96%, v/v), although some modifications have been described. These are:

- extracting in boiling 80% ethanol overnight and the following morning a further extraction for 5 min with boiling 20% ethanol;
- three extractions for 5 min with 80% boiling ethanol;
- extraction in hot 80% methanol and then extraction by boiling in 80% methanol at 60°C; and

- extraction in cold 80% ethanol stored at  $-13^{\circ}\text{C}$  for 14 h to precipitate insoluble material.

After centrifugation, the supernatant is heated at  $60^{\circ}\text{C}$  for 20 min and then dried. To the dry residue, cold 80% ethanol is added, and then heated again to dryness. The procedure is repeated three times under the same conditions.

For extraction of mannitol, sorbitol, and inositol from fruit pulps, homogenization and extraction with 80% methanol ensures the best recovery; 50% ethanol provides higher yield than 89% ethanol. After 15 min refluxing, the supernatant can be filtered. Extraction of pinnitol, mannitol, sorbitol, and inositol from Australian plants is performed with 5% perchloric acid at  $4^{\circ}\text{C}$  and then adjusted to pH 3–3.5 with  $1.0\text{ mol l}^{-1}$  potassium carbonate. Samples are purified by using Sep-Pak  $\text{C}_{18}$  cartridges preconditioned with methanol and Milli-Q purified water; the loaded cartridges are washed with deionized water and then 30% (v/v) acetonitrile in  $1.0\text{ mol l}^{-1}$  hydrochloric acid is passed through the cartridge and collected. In order to avoid acid hydrolysis of sucrose in fructose and glucose, samples are dissolved in 50% (v/v) ethanol together with  $0.1\text{ mol l}^{-1}$  imidazole buffer, pH 7.0.

Another procedure for extraction of polyols consists of grinding the tissue for 1 min at 20 000 rpm. The homogenate is centrifuged at 20 000g at  $4^{\circ}\text{C}$  for 10 min and the supernatant solution passed through a column ( $1 \times 2\text{ cm}$ ) of a styrene-divinylbenzene resin, strongly basic cation exchanger with active sulfonic groups, 200–400 mesh ( $\text{H}^{+}$ ), and after this another column ( $1 \times 2\text{ cm}$ ) of the same resin, 200–400 mesh ( $\text{Cl}^{-}$ ). The residue obtained by evaporation of the eluate is dissolved in a solvent suitable for chromatography.

For extraction of inositol phosphates from nonradioactively labeled cell or tissue specimens, cell suspensions are directly mixed with ice-cold perchloric acid to give a final acid concentration of  $0.5\text{ mol l}^{-1}$ . This extract should be free of sulfate and low in phosphate, ethyleneglycol bis(2-aminoethyl ether)- $\text{N,N,N',N'}$ -tetraacetic acid and other multicharge anions. Tissue specimens are either freeze-clamped or focused-microwave-irradiated. Frozen specimens are powdered in a liquid- $\text{N}_2$ -cooled steel-ball mill and the frozen powder cooled on ice. They are homogenized in 2 ml of ice-cold  $0.5\text{ mol l}^{-1}$  perchloric acid for 20 s. After removal of the precipitate formed after 20 min on ice by centrifugation, the 5000g supernatant is adjusted to pH 5 by adding potassium hydroxide, and the potassium perchlorate precipitate formed after 20 min on ice is removed by centrifugation. Nucleotides are removed by charcoal treatment.

If samples contain many salts, these are diluted with water and applied to a column containing 0.5 ml of Q-Sepharose (adjusted to the chloride form). After washing twice with 4 ml of  $2.5 \text{ mmol l}^{-1}$  hydrochloric acid, inositol phosphates are eluted with  $2 \times 2.5 \text{ ml}$  of  $0.6 \text{ mol l}^{-1}$  hydrochloric acid. The eluate is frozen and freeze-dried to remove the acid. Dried sample is dissolved in  $2.2 \text{ ml}$  of  $5 \text{ mmol l}^{-1}$  sodium acetate, pH 5.0. For subsequent  $^1\text{H}$  nuclear magnetic resonance (NMR) and  $^{13}\text{C}$  NMR spectra, dried extracts containing polyols are dissolved in  $0.7 \text{ ml}$  of deuterium oxide (99.996% deuteration) and the pH value adjusted to either 6.0 or 9.0 by adding deuterated formic acid and deuterated ammonia.

### Separation Methods

Chromatographic and electrophoretic methods are used for the isolation of sugar alcohols.

**Paper chromatography (PC)** Owing to the similar  $R_f$  values of monosaccharides and sugar alcohols, the distinction between these groups and between the stereoisomeric sugar alcohols may be very difficult. Chromatographic separation of the stereoisomeric sugar alcohols is achieved using solvents allowing the formation of ionic complexes of sugar alcohols with borate. For paper chromatograms, special filter paper (Whatman) is used. Solvent systems are listed in Table 1. Isopropanol–pyridine–water–acetic acid solvent has the useful property of migrating sugars, polyols, uronic acids, purine, and pyrimidine ribosides and their phosphate esters all within the  $R_f$  range of 0.1–0.9.

**Paper electrophoresis (PE)** Prior to PE separation of sugar alcohols into tetrityls, pentitols, etc., separation by paper or thin-layer chromatography (TLC) is recommended. Basic lead acetate ( $0.178 \text{ mol l}^{-1}$ ) is the most useful electrolyte; the run takes 3 h at 800 V. Other systems used are  $0.05 \text{ mol l}^{-1}$  borate, run for 1.5 h at 500 V, or  $0.2 \text{ mol l}^{-1}$  calcium acetate in  $0.2 \text{ mol l}^{-1}$  acetic acid run for 2 h at 670 V.

**Thin-layer chromatography** The velocity of separation in TLC is superior to PC and the quality of separation is similar in both techniques. Resolution of isomers has not been very satisfactory with solvent systems such as *n*-butanol–acetic acid–water saturated with boric acid (9:6:3:1, v/v/v/v) employing silica gel-coated plates. Separation is improved when silica gel plates are sprayed with  $0.5 \text{ mol l}^{-1}$  sodium dihydrogen phosphate in 50% ethanol, allowed to dry for 15 min, and then activated by heating to  $110^\circ\text{C}$  for

**Table 1** Solvent systems used in the separation of sugar alcohols by PC

<i>Solvent system</i>	<i>Proportion (v/v)</i>
Ethyl methyl ketone–acetic acid–water saturated with boric acid	9:1:1
Ethyl acetate–pyridine–water saturated with boric acid	60:25:10
1-Butanol– $0.75 \text{ mol l}^{-1}$ boric acid	85:10
<i>n</i> -Butanol–acetic acid–water	4:1:5 or 5:1:2
<i>n</i> -Butanol–ethanol–water–concentrated $\text{NH}_4\text{OH}$	45:5:49:1
Ethyl acetate–acetic acid–water	14:3:3
<i>n</i> -Butanol–ethanol–water	4:1.1:1.9
Isopropyl alcohol–pyridine–water–acetic acid	8:8:4:1

60 min. The solvent system consists of isopropanol–acetone– $0.2 \text{ mol l}^{-1}$  lactic acid (60:30:10, v/v/v), which must be made up freshly.

**‘Column’ chromatography** The technique involves elution of sugar alcohols from a column packed with charcoal, celite, cellulose, and other adsorbents. Solvent systems employed are similar to those described for PC.

Cation-exchange resins in the calcium or barium form have also been employed. A column of styrene–divinylbenzene resin, 8% cross-linked (220–400 mesh,  $\text{Ba}^{2+}$  form) can separate mannitol, sorbitol, and xylitol. Borate buffers are used as eluents from 5 to  $40 \text{ mmol l}^{-1}$ . Sugar alcohols can also be separated in Dowex 450W  $\times 2$  (200–400 mesh,  $\text{Ca}^{2+}$  form) columns by using only water as an eluent.

Recently, the use of a quite small column, namely  $14.0 \times 2.2 \text{ cm}$  of Dowex 50W  $\times 4$  in the  $\text{Nd}^{3+}$  form eluted with water at a rate of  $50 \text{ ml h}^{-1}$ , has been described for the separation of D-mannitol, D-glucitol, and D-iditol. The separation is thought to be caused by the different strength of complex formation between different polyols and metal cations that depends on the relative positions of the complexing hydroxyl groups.

**Gas–liquid chromatography** This technique allows the quantitative and qualitative estimation of sugar alcohols. It is limited by the volatility and stability of derivatives and by the accuracy with which quantitative conversion of polyols to their volatile derivatives can be achieved. The volatile derivatives of sugar alcohols commonly used are trimethylsilyl (TMS) ethers. To prepare TMS derivatives, samples are dried, dissolved in pyridine, and reacted by sequential addition of two volumes of hexamethyldisilazane (HMDS) and one volume of trimethylchlorosilane (TMCS). Other

silyl donor reagents can be used. All free hydroxyl groups are converted to the TMS ether as follows:

The reaction is carried out for 1 h at 70°C or for 24 h at room temperature. Since all solvents with free hydroxyl groups will react with HMDS and TMCS, it is necessary to exclude water at all stages of derivative preparation (i.e., by using anhydrous magnesium sulfate). The nonpolar phases give the best results for the separation of TMS derivatives of sugar alcohols. Stationary phases used include 2–5% silicon SE 30 or SE 52 (poly(dimethyl siloxane)), QF-1 (poly(methyltrifluoropropyl siloxane)), and EGS (poly(ethylene glycol succinate)) on uncoated adsorbent from diatomite (an acid washed and silanized diatomaceous earth support), acid-washed and dimethylchlorosilane-treated (AW DMCS). Examples of stationary phases are given in Appendix A.

Acetate derivatives of polyols show certain advantages for GC compared with TMS ethers: they are more stable, unaffected by water and other solvents containing free hydroxyl groups, and are freely soluble in the pyridine used for their preparation. Acetate derivatives are generally prepared by the action of acetic anhydride in the presence of a suitable catalyst. Reaction is carried out for 1–4 h at 70°C. Free hydroxyl groups are converted to the acetyl esters, so that substitution occurs on all carbon atoms of the polyols, and all but one of the aldoses. In the most widely used method, the sample is dried and treated with equal volumes of acetic anhydride and pyridine, which can be substituted with sulfuric acid and sodium acetate.

The best separations of polyols have been achieved on mixed phase packings, which combine the high resolving capacity of the polar phase with the stability of the nonpolar phase. Reported stationary phases are 2–10% EGSS-X (ethylene glycol succinate copolymerized with dimethyl polysiloxane) or ECNSS-M (ethylene glycol succinate copolymerized with cyanopropyl polysiloxane) on uncoated adsorbent from diatomite, acid washed, and dimethylchlorosilane-treated or uncoated adsorbent from diatomite acid-washed and silanized, 3% XE-60 (poly(methyl cyanopropyl siloxane)) on uncoated adsorbent from diatomite acid-washed and silanized, GP 3% SP-2340 (poly(dicyanopropyl siloxane)) on diatomite support and many other combinations.

Mannitol, sorbitol, and inositol separation is performed on a DB-5 or DB-1 (Durabon) fused silica capillary column of 30 m × 0.24 mm,  $d_f = 0.25 \mu\text{m}$ , with programmed temperature. These polyols can also be separated on fused silica columns coated with

CP-Sil-5CB (poly(dimethyl siloxane)), film thickness 0.12  $\mu\text{m}$ , and a temperature program without resorting to methoximation of sugars. Capillary gas chromatography with a phenyl (50%) dimethylpolysiloxane phase has been validated for the simultaneous determination of D-pinitol, *myo*-inositol, and their derivatives, as trimethylsilyl-derivatives.

Methyloxime-acetyl derivatives of sugar alcohols that avoid interference due to monosaccharides and resolve isomeric hexitols have been described. The procedure is as follows: 0.5 ml of methoxylamine hydrochloride in pyridine (10 mg ml<sup>-1</sup>) is added to dried samples containing polyols, and then incubated at 70°C for 30 min. The specimens are acetylated by adding 0.5 ml of acetic anhydride for a further 10 min at 70°C. Two drops of methanol are added and solvents evaporated in a water bath at 30°C under a stream of air. The residues are desiccated for at least 1 h and then dissolved in 50  $\mu\text{l}$  of methanol to be chromatographed. The column was filled with 3% XE-60 (80–100 mesh) and the chromatograph operated at a column temperature of 230°C with nitrogen as carrier gas at a flow of 50 ml min<sup>-1</sup>. **Figure 3** shows a chromatogram obtained using an aqueous solution containing 10 sugar alcohols.

**Liquid chromatography** LC provides a rapid separation of sugar alcohols for analytical purposes without the need for sample derivatization. Extracts cannot be used directly in LC since substances such as proteins, lipids, and salts rapidly may inactivate the column packing; in any case, purification prior to chromatography must be carried out. Solutions can be deproteinized, e.g., by adding potassium hexacyanoferrate(III) (15%, w/v) and zinc acetate (30%, w/v) solutions. Alternatively, TCA can be used. The excess acid is subsequently removed by partitioning with six volumes of diethyl ether. The protein-free extracts are passed through a 0.22  $\mu\text{m}$  pore filter before chromatography.

Separation may be accomplished using adsorption chromatography, straight or reversed-phase partition chromatography, and ion-exchange (cation and anion) chromatography. Most useful for the separation of sugar alcohols are cation-exchange resins, using water or borate buffer as mobile phase. The optimum temperature range depends on the column, normally from 50°C to 80°C. **Figure 4** shows an LC separation of a standard mixture of three polyols.

The combined use of parabens as preservatives and the polyols as sweeteners or stabilizers is very extensive in the pharmaceutical, cosmetic, and food industries. However, it has been proved that these mixtures are not stable, because a slow *trans*-esterification reaction takes place, yielding different

degradation products, such as *p*-hydroxybenzoic acid, with lower preservative properties. Thus, the appearance of these degradation products should be controlled to guarantee the preservative capability of the paraben formulation. Sorbitol, which is one of these frequently used polyols, reacts with methylparaben (MPB) to form the ester sorbitol-paraben (SPB). MPB and SPB can also hydrolyze to form *p*-hydroxybenzoic acid and both reactions reduce the preservative capability of the formulation. An HPLC method by using  $C_{18}$  column with mobile phase of methanol–water (30:70, v/v) has been developed to separate the mixture of SPB.

From 1996 to the present, many stationary phases have been used. For the separation of sorbitol from other mono- and disaccharides, stationary phases prepared by the reaction of porous particles of chloromethylated styrene–divinylbenzene copolymer with various amines are preferred. Because of subtle differences in the  $pK_a$  values of hydroxyl groups, the oxyanions of carbohydrates generated under alkaline conditions interact with the positively charged stationary phase and facilitating their separation by the anion-exchange mechanism.

**Figure 4** HPLC separation of a standard mixture of 10 µg each of D-ribose, ribitol, arabinol, and mannitol on a MicroPak SP  $NH_2$ -5 (4 mm ID  $\times$  150 mm) column. Solvent, acetonitrile–water (80:20, v/v), isocratically. Flow rate, 1.3 ml min<sup>-1</sup>. Peaks: 1 = D-ribose as internal standard; 2 = ribitol; 3 = arabinol; 4 = mannitol. The line drawn across the chromatogram indicates baseline correction.

Widely utilized is the Dionex™ systems with an anion-exchange column, CarboPac PA1 and CarboPac MA1 (4  $\times$  250 mm) with a guard column (4  $\times$  50 mm). By using CarboPac MA1 and 16 mmol l<sup>-1</sup> NaOH as eluent, 30 different carbohydrates and alcohols can be separated: their migration times for alditols ranging from 10.7 min of erythritol to 27.7 min for maltitol. This column is able to separate a more wide variety of alcohols, sugar alcohols, and carbohydrates than the CarboPac PA1 optim, although retention times in the latter column are much lower.

Sorbitol is separated on a cationic exchange column (Sugar-Pak I), using 0.01 mol l<sup>-1</sup> potassium dihydrogen phosphate, pH 2.6, in isocratic mode, as mobile phase. Maltitol, *iso*-maltitol, and lactitol are separated by high-pH anion-exchange chromatography using a CarboPac PA100 with guard column using 40 mmol l<sup>-1</sup> sodium hydroxide and 1.0 mmol l<sup>-1</sup> barium acetate as the mobile phase (see Table 2). A new sulfonated monodisperse resin-based column (PL Hi-Plex) in protonated form has been developed and it is especially useful for profiling both carbohydrates and organic acids by combining mechanisms of ion exclusion and partition. Mannitol, sorbitol, maltitol, maltotriitol, lactitol, xylitol, and maltotetraitol have been separated on this column.

**Capillary electrophoresis** CE is a powerful separation technique that can provide high-resolution efficiency. One methodological difference between CE and LC is that CE utilizes an open tubular capillary. In CE, even if the samples contain a matrix, it can be injected with minimal sample preparation. In CE, ionic species are separated based on their charge and size; therefore, the electrolyte pH can be an important factor in optimizing resolution. Since  $pK_a$  values of neutral sugars and sugar alcohols are high (from 12 to almost 14), strongly alkaline conditions must be used to ensure ionization. Borate buffer from 20 to 75 mmol l<sup>-1</sup>, at pH values ranging from 10 to 13 has been used as BGE. Mannitol, sorbitol, galactitol, xylitol, and inositol are separated from other acidic, neutral, and amino sugars by CE using 2,6-pyridine dicarboxylic acid (PDC) and cetyltrimethyl ammonium bromide (CTAB) at pH 12.1 as electrolyte to reverse the direction of electroosmotic flow. Cetyltrimethyl ammonium hydroxide (CTAH) can also be used instead of CTAB.

**Other separation methods** Sorbitol and their paraben derivatives have been separated by micellar electrokinetic chromatography by using 25 mmol l<sup>-1</sup> phosphate buffer, pH 7.0, containing 100 mmol l<sup>-1</sup>

**Table 2** Mobile phase composition and elution mode of some sugar alcohols analyzed by anion-exchange chromatography-pulsed amperometric detection

Sugar compounds	Mobile phase composition and elution mode
Monosaccharides, alditols	8.0 mmol l <sup>-1</sup> Ba(OH) <sub>2</sub> and 0.5 mmol l <sup>-1</sup> HOAc, and 1.0 mmol l <sup>-1</sup> Ba(OH) <sub>2</sub> and 0.125 mmol l <sup>-1</sup> HOAc
<i>myo</i> -Inositol	1.0 mol l <sup>-1</sup> NaOH isocratic
Mannitol and glucose	480 mmol l <sup>-1</sup> NaOH
Mono- and disaccharides, alditols, aminosugars	5, 10, or 20 mmol l <sup>-1</sup> NaOH and 1–2 mmol l <sup>-1</sup> Ba(OAc) <sub>2</sub>
Alditols, mono-, and disaccharides	Water and postcolumn base addition
Alditols	0.5 mol l <sup>-1</sup> NaOH
Ribitol	650 mmol l <sup>-1</sup> NaOH
Alditols and sugars	0.6 or 0.45 mol l <sup>-1</sup> NaOH
Alditols and sugars	0.5 mol l <sup>-1</sup> NaOH and 1.0 mmol l <sup>-1</sup> Sr(OAc) <sub>2</sub> , Ba(OAc) <sub>2</sub> , or Ca(OAc) <sub>2</sub>
Alditols and sugars	0.58 mol l <sup>-1</sup> NaOH and 2.0 mmol l <sup>-1</sup> Ba(OAc) <sub>2</sub>
Alditols of mono- and disaccharides	0.5–0.6 mol l <sup>-1</sup> NaOH; 40 mmol l <sup>-1</sup> NaOH, and Ba(OAc) <sub>2</sub> ; 75 mmol l <sup>-1</sup> NaOH and Ba(OAc) <sub>2</sub>
Monosaccharides and alditols	NaOH gradient
Alditols, mono-, and oligosaccharides	0.1 mol l <sup>-1</sup> NaOH and NaOH and acetate gradient oligosaccharides

sodium dodecyl sulfate, over the critical micellar concentration, as BGE.

Capillary isotachopheresis (ITP) method with conductimetric detection has been proposed for separating polyols, such as mannitol, sorbitol, dulcitol, and xylitol. To facilitate the electromigration of the polyols, the strategy based on their conversion to anionic species by complex formation with B(III) as the central ion was adopted. The hydroxyl groups of the polyols react rapidly with borate to give anionic complexes that could presumably be separated by ITP. The complex-forming agent, i.e., boric acid, serves as the terminator and thus, *in situ* conversion of the neutral analytes to ionic species took place only during ITP analysis. The operational electrode system consisted of 10 mol l<sup>-1</sup> hydrochloric acid and 20 mmol l<sup>-1</sup> imidazole, pH 7.0, as the leading electrolyte, and 20 mmol l<sup>-1</sup> boric acid, pH 8.0, as the terminating electrolyte.

Subcritical fluid chromatography (SubFC) analysis of nine monosaccharides and three polyols, *meso*-erythritol, xylitol, and mannitol, on silica phases has been developed. Mobile phase composition was CO<sub>2</sub> modifier (80:20, v/v), the modifier being MeOH–water–triethylamine (91.5:8.0:0.5, v/v/v). In SubFC, the addition of triethylamine slightly increase the retention since interactions with the solutes and/or a strong interaction with the silanols and the residual silanols can occur.

## Detection Methods

**Spectrophotometric detection** Polyols can be determined by estimating the formaldehyde produced after mild periodate oxidation using arsenic(III) oxide

to destroy the excess periodate before addition of the chromogenic solution. Periodate oxidation is carried out at pH 4.5 for exactly 1 min, the periodate consumption being measured spectrophotometrically.

**Detection of spots on paper and thin-layer chromatograms** The similar *R<sub>f</sub>* values of monosaccharides and sugar alcohols in PC and TLC necessitate the use of specific detection reagents for sugar alcohols, i.e., benzidine–sodium periodate or reaction of monosaccharides with triphenyltetrazolium chloride prior to chromatography. Polyols can be identified with alkaline silver nitrate after composing the boric acid–sugar complex (if necessary) with hydrofluoric acid. Another alternative is the identification of polyols with *p*-anisidine phosphate, a characteristic reagent for sugars. Polyols appear colorless while spots of sugars are colored if brown cellulose paper previously dyed by the action of the acidic reagent is used. Mobilities and color of spots of some polyols are listed in Table 3. For PE, the paper strips are dried at 100°C and the color of sugar alcohols developed with 2.5% (w/v) potassium permanganate–chromium trioxide reagent.

Thin-layer plates may be developed by spraying with aniline–diphenylamine–acetone–80% phosphoric acid (4 ml:4 g:200 ml:30 ml) followed by heating at 105°C for 30 min. The combination of the <sup>14</sup>C isotope technique with PC is still one of the best methods, not only for the detection of sugar alcohols but also for the determination of their turnover and elucidation of their biosynthesis. Radioactive spots are eluted from chromatograms, evaporated on to planchettes, and the radioactivity measured with a counter.

**Table 3** Movement and detection of polyols in PC with Whatman No. 4 paper after 2 h at 30°C with isopropanol–pyridine–water–acetic acid (8:8:4:1, v/v/v/v) as mobile phase and separation by TLC in layers of phosphate-impregnated SilicaGel 60

Polyol	Reagent solution		$R_f^a$	$R_f$ in TLC

<sup>b</sup>Colors of spots: W = white; Y = yellow.

**Detection in GC** The universal detector for TMS and acetate derivatives of sugar alcohols is the flame ionization detector (FID). Linear response of the FID has been established for such an analysis. Detector temperatures in the gas chromatograph vary from 250°C to 300°C.

GC–MS methods for the simultaneous quantitation of sugars, sugar alcohols, and acids, measures as their TMS-oxyme ether/ester derivatives, has been developed. The reproducible determination of analytes was performed both on the basis of total ion current and selected fragment ions values.

**Detection in LC** Carbohydrates, as well as carboxylic acids, are difficult to detect by conventional spectrophotometric methods because they lack suitable chromophores or fluorescent groups. Sugar alcohols can be detected by refractive index change or by postcolumn reaction. Refractivity measurement is not specific for sugar alcohols and detectors are incompatible with gradient programs of the mobile phase. Detection of polyols can be achieved using an UV absorbance detector at 195 nm, which improves the sensitivity of polyol determination. In this case, it is absolutely necessary to use the purest mobile phases that are possible. Precolumn derivatization of sorbitol and galactitol with phenylisothiocyanate gives UV-absorbing derivatives with an absorbance maximum at 240 nm. A nonradiometric LC technique, employing dephosphorylation in an enzyme-loaded postcolumn reactor and subsequent orthophosphate

determination has been described for inositol polyphosphate isomers, based on molybdophosphate formation but requires relatively large amounts of tissue. A new dye-based ternary-complexometric technique not requiring dephosphorylation is based on the finding that transition-metal(III) ions bind with very high affinity to both 4-(2-pyridylazo)-resorcinol (PAR) and polyanions like inositol phosphates. In this two-ligand one-metal system, the dye functions as a reporter substance, indicating optically the presence of competitive ligands. This technique has been termed ‘metal-dye detection’. **Figure 5** shows a separation of a standard mixture of nucleotides and inositol polyphosphates by LC with metal-dye detection.

The tendency of polyols to form chelate complexes with some central ions, such as B(III), Ge(IV), or Mo(VI) is of analytical importance since the complex formation is accompanied by the liberation of protons from the polyol molecule that are normally not split off in aqueous medium. The pH changes occurring due to complex formation has been utilized in the potentiometric or spectrophotometric determination.

Electrochemical detection (potentiometry and amperometry) has been recognized as a useful method following separation by LC. A number of methods based on electrochemical oxidation using various metallic electrodes has been reported. Foiling of gold and platinum electrodes may be overcome by pulsed amperometric detection, which combines amperometric detection with alternate anodic and cathodic

**Figure 5** HPLC-m.d.d. analysis of a standard mixture of nucleotides and  $\text{InsP}_x$ . Separation was performed on a  $15\text{ cm} \times 0.5\text{ cm}$  Mono Q column. Eluent A and B contained  $9$  and  $14\text{ }\mu\text{mol l}^{-1}$   $\text{YCl}_3$ , respectively, and reagent C contained  $200\text{ }\mu\text{mol l}^{-1}$  PAR. The flow rate was  $1.2\text{ ml min}^{-1}$  for A/B, and  $0.6\text{ ml min}^{-1}$  for C. The gradient applied is depicted. The upper monitor tracing (A) was obtained by m.d.d. at  $546\text{ nm}$ , the lower one (B) by UV detection. The components of the nucleotide mixture are given in the lower tracing. The mixture of  $\text{InsP}_x$  was from partly hydrolyzed  $\text{InsP}_6$ . An equivalent of  $10\text{ nmol}$  of  $\text{InsP}_x$  was injected. Assignments are in part based on pure standard available. Assignments of isomers to individual peaks thus possible are indicated by an asterisk:  $1 = \text{P}_i + \text{InsP}$ ;  $2 = \text{Ins}(1,2)\text{P}_2^* + \text{Ins}(1,6)\text{P}_2^*$ ;  $3 = \text{PP}_i$ ;  $4 = \text{unidentified}$ ;  $5 = \text{Ins}(1,3,5)\text{P}_3^* + \text{Ins}(2,4,6)\text{P}_3^*$ ;  $6 = \text{Ins}(1,3,4)\text{P}_3^*$ ;  $7 = \text{Ins}(1,2,3)\text{P}_3^* + \text{Ins}(1,2,6)\text{P}_3^* + \text{Ins}(1,4,5)\text{P}_3^*$  preceding  $\text{Ins}(2,4,5)\text{P}_3^*$ ;  $8 = \text{Ins}(1,5,6)\text{P}_3^*$ ;  $9 = \text{Ins}(4,5,6)\text{P}_3^*$ ;  $10 = \text{Ins}(1,2,3,5)\text{P}_4^* + \text{Ins}(1,2,4,6)\text{P}_4^*$ ;  $11 = \text{Ins}(1,2,3,4)\text{P}_4^* + \text{Ins}(1,3,4,6)\text{P}_4^*$ ;  $12 = \text{Ins}(1,3,4,5)\text{P}_4^*$ ;  $13 = \text{Ins}(1,2,5,6)\text{P}_4^*$ ;  $14 = \text{Ins}(2,4,5,6)\text{P}_4^*$ ;  $15 = \text{Ins}(1,4,5,6)\text{P}_4^*$ ;  $16 = \text{Ins}(1,2,3,4,6)\text{P}_5^*$ ;  $17 = \text{Ins}(1,2,3,4,5)\text{P}_5^*$ ;  $18 = \text{Ins}(1,2,4,5,6)\text{P}_5^*$ ;  $19 = \text{Ins}(1,3,4,5,6)\text{P}_5^*$ ;  $20 = \text{InsP}_6$ . a = AMP + CMP + NAD; b = cyclic AMP; c = GMP; d = NADH; e = UMP; f = NADP; g = ADP + ADP-ribose; h = ATP + CTP; i = GDP; k = IDP; l = GTP; m = UDP; n = ITP; o = UTP. polarization to clean and reactivate the electrode surface. However, constant potential amperometric is preferred because of its instrumental simplicity. Metals such as Cu, Ni, and Ag, as well as chemical modified electrodes, have been developed for the electrocatalytic oxidation of carbohydrates in alkaline media. Mobile phases consist of high concentration of sodium hydroxide ( $0.1\text{--}0.7\text{ mol l}^{-1}$ ), isocratically or in gradient with water containing or not containing the same modifiers. Eluent modification with barium ions enhances both the amperometric response and the chromatographic data reliability without column regeneration and postcolumn addition of strong bases. The cobalt-modified

electrode, prepared by anodic electrodeposition of cobalt oxyhydroxide on the polished glassy carbon surface by voltage cycling, has been used to detect inositol, xylitol, sorbitol, and mannitol from complex mixtures of carbohydrates. It is known that in alkaline medium the high valence states of the cobalt oxyhydroxides show interesting electrochemical activity toward the electrooxidation of several polyhydric organic compounds and, thus, catalytic oxidation of alditols occurs at potentials higher than  $0.3\text{ V}$  versus SCE.

Cooper wire electrodes, used for amperometric and potentiometric detection in HPLC, have been developed for the simultaneous detection of sugars,

polyols, and carboxylic acids. Diluted solutions of acids on water have been used as the eluent for the separation of carbohydrates and carboxylic acids in ion-exclusion chromatography and as the carrier for the potentiometric detection, with postcolumn addition of sodium hydroxide as the electrolyte for the amperometric detector.

Precolumn derivatization of sugar alcohols with a chromophoric reagent, such as phenylisocyanate, benzoate, and 2,4-dinitrobenzoate allows the use of inexpensive UV detectors. *p*-Nitrobenzoyl chloride was found to be a rapid and quantitative derivatizing agent for sugar alcohols since strong UV-absorbing derivatives at 260 nm are produced.

**Detection in CE** Since carbohydrates lack both a charge and a strong UV chromophore, several derivatization techniques have been described. Very recently, a new method based on precapillary derivatization with luminol (3-amino-phthalhydrazide) for carbohydrate analysis has been proposed with online chemiluminescence detection. While this method leads to improved sensitivity and resolution, the complexity of derivatization limits its use. Alternatively, methods for the analysis of underivatized carbohydrates have been developed. These methods include the use of high alkaline electrolyte to ionize carbohydrates and make them suitable for indirect UV detection. Mannitol, sorbitol, galactitol, xylitol, and inositol have been detected with indirect UV detection using PDC and CTAB/CTAH as electrolytes.

### Identification Methods

In the analytical procedures described above, spot or peak identification is based on a comparison of  $R_f$  or retention time of unknown spots or peaks with those of authentic compounds, followed by cochromatography to obtain coincident spots or peaks on the chromatogram. Further analyses using different stationary phases and derivatives provide unique combinations of retention values based on various physical and chemical characteristics. MS offers a good potential when coupled to GC.

The structure of some universal polyols can also be confirmed by NMR techniques, involving  $^{13}\text{C}$  and  $^{31}\text{P}$  NMR. *myo*-Inositol-1,3,4,5,6-pentakisphosphate has been identified by these techniques in avian erythrocytes after separation of inositol polyphosphates by Dowex 1  $\times$  2 chromatography. Arabitol, mannitol, and ribitol have also been identified using natural abundance criteria by  $^{13}\text{C}$  NMR spectroscopy in a number of lichen species.

### Areas of Special Interest

Acyclic sugar alcohols are considered as the most important agents for osmosis in plants, related to the maintenance of the water potential in many lower and higher plants living in arid conditions. Many lichens accumulate erythritol, mannitol, arabitol, or sorbitol as the main system to maintain a convenient, residual amount of water to survive. However, a balanced [polyol]/[hexose] ratio is required to avoid catabolite repression of many enzymes related to amino acids and phenolics metabolism.

In plants and animals, phosphoinositides are involved in the permeation mechanism for calcium ions. This mechanism is the basis of membrane potential changes that produce signal transduction and transmission of electrical stimuli. General physiological functions, such as neural transmission, memory, and vision in animals, or phytochrome-regulated morphogenesis in plants, are started by a cascade process involving phosphoinositide metabolism. For example, hydrolysis of phosphatidylinositol-(4,5)-bisphosphate (PTDIns(4,5) $\text{P}_2$ ) leads to inositol-(1,4,5)-triphosphate (Ins(1,4,5)- $\text{P}_3$ ) and diacylglycerol, the latter well known as an activator of protein kinases. Also calcium ions, released from their intracellular stores after the binding of Ins(1,4,5) $\text{P}_3$  to its endoplasmic reticulum receptor, activates protein kinases.

Sugar alcohols are widespread in food and beverages because they contribute to the nutrition value, flavor, and organoleptic characteristics of foods. Polyols have reduced cariogenic properties. The low hygroscopicity and the high stability of polyols have provoked a growing interest in food industry. Polyols are often claimed to be useful sweeteners, specially for diabetics. However, this is not true; polyols affect the blood glucose level (through slower than sucrose). Besides polyols contain calories; they have energy values of  $10\text{ kJ g}^{-1}$  on average, compared to  $17\text{ kJ g}^{-1}$  of sucrose and, therefore, must be accounted for the meal planning of diabetics. The polyols are often used in confectionery products, such as chewing gum pastilles, chocolate, candy, sugar-free candy, and cakes. Xylitol, sorbitol, mannitol, isomalt, and maltitol are the main polyols used in food products. Mannitol, sorbitol, and xylitol are pharmaceutically important nonionic osmotic diuretics.

### Sources of Error

Analysis of complex mixtures containing several polyols requires some attention to the possibility of analyte loss. Polyols have different solubilities in solvent currently used in extraction and

chromatography. Most acyclic polyols are freely soluble in water whereas the water solubility of inositol and inositol derivatives is limited. For example, a saturated solution of sorbitol in water contains ~89% (w/v) of this polyol whereas the limit of inositol solubility in water at 25°C is 140 g l<sup>-1</sup>. By contrast, inositol and inositol monophosphate are practically insoluble in pure ethanol. However, phytic acid is slightly soluble in pure ethanol and methanol whereas sorbitol is quite soluble in hot ethanol and sparingly soluble in cold alcohol.

All of polyols are very stable in the cold even when they are mixed with diluted acids, alkalis, or mild oxidizing agents. Inositol-1-phosphate is remarkably resistant to hydrolysis by boiling with strong alkali, although it can be hydrolyzed by boiling with 6 mol l<sup>-1</sup> hydrochloric acid for 14 h. Phytic acid decomposes slightly on heating.

### Introduction

Starch is a polymer of glucose, existing in two basic configurations. Amylose is predominantly a linear chain polymer, composed mostly of  $\alpha$ -1,4 linkages. Amylopectin is a branched polymer containing  $\alpha$ -1,4 and  $\alpha$ -1,6 bonds. The amylose fraction also has some degree of branching. Starch is found widely distributed in nature and is present in high concentration in cereal grains, in potatoes, and in roots such as manioc. It is the major complex carbohydrate in the diet of humans. Processes have been developed on an industrial scale to separate starch from the starch-rich sources. Starch is the starting material for the manufacture of glucose syrups and modified starches, and this family of products finds wide application in food and industrial use.

In every area of its use and manufacture, a need exists for measurement of starch. The industrial preparation of starch is based on wet-milling, and the efficiency of the process determines the purity of the final product. Analysis of the starting raw material, the starch, all by-products, and the factory wastewater, is necessary to assess the separation procedure. Starchy foods are favored by nutritionists, and labeling of foods with compositional data becomes the norm.

### Polarimetric Methods

Dissolution of starch can be achieved by various means, but there is usually associated hydrolysis. Once a solution is obtained, then the optical activity of the starch can be utilized for quantification. Two long-established methods are in common use.

#### Ewers Method

The first is based on controlled partial hydrolysis of the starch with hydrochloric acid, and was proposed in 1908 by Ewers. First, 2.5 g of sample is added to a 100 ml volumetric flask and dispersed in 50 ml of 1.128%, m/v, hydrochloric acid. The flask is plunged into a vigorously boiling water bath, with agitation,

and after 15 min precisely, the contents are diluted, and the flask is cooled in an ice bath. Before making-up, protein is precipitated with Carrez reagent (zinc acetate + potassium hexacyanoferrate(II)). Following filtration, the optical rotation is measured. To account for 'nonstarch' carbohydrate present, the sample is extracted with 40%, v/v, ethanol. This solution is hydrolyzed with acid, the optical rotation is measured, and its contribution is subtracted from the total analysis figure. Starches from different sources hydrolyze in acid at different rates, and Ewers had experimentally determined a factor for specific starch types.

The starch content of the sample is calculated according to eqn [1]:

$$\% \text{ Starch} = \frac{2000(P - P')}{[\alpha]_{\text{D}}^{20}} \quad [1]$$

with cell path length = 200 mm, sample weight = 2.500 g, and where  $P$  is the total optical rotation in degrees;  $P'$  is the optical rotation, in degrees, of substances soluble in 40% ethanol;  $[\alpha]_{\text{D}}^{20}$  is the specific optical rotation of the pure starch; and 2000 represents the diminution of the mathematical terms for the conditions of the analysis.

Conventionally accepted factors for different starch types are:

- Maize starch + 184.6°
- Wheat starch + 182.7°
- Potato starch + 185.4°
- Rice starch + 185.9°
- Barley starch + 181.5°
- Oat starch + 181.3°
- Other types of starch and mixtures + 184.0°

This method is widely used in Europe, and is proposed by many legislative bodies including the European Commission. It is an empirical method and therefore has the inherent obligation of strict adherence to the protocol, and the possibility of operator dependence.

#### Calcium Chloride Dissolution

An alternative method depends on the ability of concentrated solutions of electrolytes to solubilize starch. Clendenning in 1945 developed a method using a 40%, w/v, solution of calcium chloride, adjusted to pH 2.0 with acetic acid. Two grams of sample is added to an Erlenmeyer flask, dispersed in

10 ml of water, followed by addition of 60 ml of the salt solution. A few glass beads are included, and some drops of octanol are added to control foaming. A reflux condenser is fitted and the flask is heated strongly so as to reach boiling within 5 min. After 30 min of reflux, the flask is removed and cooled to room temperature. The whole content is transferred carefully to a 100 ml volumetric flask using the calcium chloride solution for all transfer and washing. Carrez reagent is added to precipitate protein, prior to final volume adjustment. Work done by Clendenning showed that a universal factor of  $203^\circ$  optical rotation could be attributed to all starches, regardless of source. Starch content is calculated accordingly to eqn [2]:

$$\% \text{ Starch} = \frac{P \times 100}{203 \times 2 \times m/100} \quad [2]$$

where  $P$  is the optical rotation of the sample, 2 is the cell path length (in dm), and  $m$  is the sample weight in grams.

While hydrolysis is less than in the Ewers method, it is still an empirical method, and some restrictions apply to both approaches. Wheat fractions with high gluten content cause excessive foaming in the calcium chloride method, and this is often impossible to diminish. In addition, both methods are suited to samples containing only granular native starch, and not gelatinized starch. Pentosans cause errors, having a negative influence on the calcium chloride method, and a positive effect with acid hydrolysis. This means that the methods are unsuitable for fractions containing wheat bran, which contains a high pentosan level. International collaborative exercises have found a tolerance of  $\sim 1.5\%$  on these two methods. Despite the drawbacks of these methods, starch manufacturers successfully use them for calculating mass balances.

## Hydrolysis Methods

### Acid Hydrolysis

Starch can be fully hydrolyzed to dextrose, which can be measured, with subsequent calculation of the original starch content. While the use of enzymes is probably the best means, acid hydrolysis is a simple alternative. Importantly, dilute acid should be used to avoid condensation of the dextrose. When 1 g of starch is refluxed for 3 h in  $0.25 \text{ mol l}^{-1}$  hydrochloric acid, the hydrolysis is complete; this has been verified by chromatography. An official method based on this approach uses the Lane and Eynon titration based on Fehling's solution to determine the dextrose. However, alternative methods for dextrose

quantification abound, and there is further discussion within this article. Some modified starches resist total hydrolysis, but the approach offers a simple fingerprint technique if liquid chromatography is applied to the hydrolysate.

### Enzyme Hydrolysis

When using enzymes, there are three important stages in the method: (1) dissolution of the starch; (2) complete hydrolysis of the starch to dextrose (glucose); and (3) accurate measurement of the dextrose.

Satisfactory dissolution of the starch at atmospheric pressure is difficult to achieve and a thermostable  $\alpha$ -amylase is often included. Pressure cooking with an autoclave at  $130^\circ\text{C}$  is better, but such equipment is uncommon in laboratories. Dimethyl sulfoxide, with 10% water included, is an excellent solvent for starch, but this water content is critical, and the organic solvent is present during the subsequent enzyme hydrolysis. However, commercial kits are available that employ dimethyl sulfoxide as solvent. Acid may also be used for dissolution but, if a large amount is used, care must be taken that the starch does not 'salt-out' on neutralization. A most convenient solvent has proved to be cold dilute sodium hydroxide solution. The starch, 250 mg, is slurried in 25 ml of water, an equal volume of  $1 \text{ mol l}^{-1}$  sodium hydroxide is added and stirring is continued for 5 min. Before addition of enzymes the solution is adjusted to pH 4.5–5.0 with acetic acid.

To ensure full conversion to dextrose, the ideal conditions for hydrolysis must be chosen. This implies excess of enzyme, low starch concentration to avoid reversion of the dextrose formed, and optimal pH. Enzymes should be of the highest purity available.

Some methods available offer the use of amyloglucosidase alone. Work done with corn and potato starches illustrated that even under ideal conditions amyloglucosidase does not fully convert starch to dextrose, although the shortfall is small. The limit dextrin was more noticeable in corn starch hydrolysis. Proof was obtained by studying the reaction kinetics, and analyzing the hydrolysates by ion chromatography using pulsed amperometric detection. There remained always a small amount of a limit dextrin, and in the case of potato starch some other low molecular mass residues.

A study done within an International Standards Organization (ISO) work group has shown that the inclusion of pullulanase effectively eliminates the limit dextrin, as shown in **Figure 1**. Hydrolysis also appears accelerated by the presence of  $\alpha$ -amylase, although the pH (4.8–5.0) is not optimal. A mixture

**Figure 1** Expanded chromatograms from Dionex ion chromatograph of enzyme hydrolysates of corn and potato starch, the use of a single enzyme, amyloglucosidase (AMG), and a mixture of AMG,  $\alpha$ -amylase ( $\alpha$ -A), and pullulanase (PU), to show the effect on hydrolysis of limit dextrin. Anion exchange column AS6, with pulsed amperometric detection. Gradient flow solvents (1)  $150 \text{ mmol l}^{-1}$  NaOH and (2)  $150 \text{ mmol l}^{-1}$  NaOH +  $500 \text{ mmol l}^{-1}$  NaOOCCH<sub>3</sub>. Postcolumn addition of  $0.3 \text{ mmol l}^{-1}$  NaOH.

consisting of amyloglucosidase (500 U), pullulanase (0.3 U), and  $\alpha$ -amylase (1440 U) proved an adequate system for complete hydrolysis of the starch. The maximum amount of starch present should be 250 mg, and the enzymes are added immediately after neutralization of the alkali. This avoids the possibility of retrogradation of the starch. However, this combination did not fully hydrolyze potato starch, as up to 2% phosphate-containing oligosaccharides can remain in the hydrolysate.

Various ways of measuring glucose exist. Probably the most often employed principle is the oxidation of glucose with glucose oxidase (GOD), to produce hydrogen peroxide and D-glucono- $\delta$ -lactone (reaction [I]):

Many methods are available in which the hydrogen peroxide, usually in the presence of peroxidase, takes part in reactions to form colored products. Typical reagents are a combination of phenol with either *p*-hydroxybenzoic acid or 4-aminopyrrole, or 2,2'-azino-bis-(3-ethyl-benzthiazoline-6-sulfonate) (ABTS) alone. Interference can be a problem; for example, ABTS is sensitive to the presence of proteins. Another drawback of colorimetric methods is that calibration with glucose is obligatory.

Hydrogen peroxide can be quantified electrochemically and a commercial instrument for glucose measurement is available, which consists of a cell containing GOD immobilized in a membrane. The hydrogen peroxide formed as the dextrose passes through the membrane diffuses to an anode where it is oxidized, and the resulting current produced is measured at the equilibrium point of the oxidation.

The most specific measurement of glucose is by a totally enzymatic procedure. D-Glucose is phosphorylated to glucose 6-phosphate (G-6-P) by adenosine 5'-triphosphate (ATP) in the presence of hexokinase (HK) (reaction [II]). Subsequently, G-6-P is oxidized by nicotinamide adenine dinucleotide phosphate (NADP) to gluconate 6-phosphate in the presence of glucose-6-phosphate dehydrogenase (G6P-DH). NADPH is formed in a stoichiometric amount with regard to the glucose present (reaction [III]). It can be quantified by absorbance at 340 nm:

All additions and reactions occur within the cuvette of the spectrophotometer, so the method is essentially semimicro. As sample size may be only

100  $\mu$ l, all micropipettes must be calibrated precisely. Better repeatability has been found by weighing all additions into the cuvette. While this procedure is theoretically superior to other approaches, its application needs the greatest care. Although the suppliers of kits quote a tolerance of  $\pm 1\%$ , this figure is optimistic, and is not derived from a collaborative study effected under ideal conditions for statistical evaluation.

With the advent of highly sensitive differential refractometers, liquid chromatography can be applied to the measurement of the glucose. Success has been achieved by acidifying the enzyme hydrolysate with sulfuric acid to inactivate the enzymes, and then chromatographing this solution directly on a cation-exchange column in the hydrogen form. An internal standard, *meso*-erythritol, should be included from the start of the analysis; baseline resolution of all components is found. This method was developed in an ISO work group, and a collaborative exercise performed on native starches yielded 98% recovery, with a tolerance of  $\pm 2\%$ .

## Choice of Method

Whereas the ideal situation is that a single method will suffice for all starch-bearing matrices, this is unlikely from a practical standpoint. For example, a customs laboratory needing daily to confirm the integrity of large series of native starches relies on official methods based on polarimetry; speed and reproducibility are the requirement. On samples that contain pregelatinized native starch, or other substances that are optically active, an enzymatic method must be used; specificity is the requirement.

The starch content of a natural product or of a man-made product may be required. The latter products might contain modified starches, and a limited number are permitted for food purposes; acetate, adipate, succinate, oxidized, hydroxypropyl. For nonfood applications cationic and carboxymethyl starches are in common use. Polarimetric methods, when applied to such modified starches, reveal that calcium chloride dissolution is better than the Ewers method. Even with cross-bonded starches, which are difficult to solubilize, complete dissolution is achieved within 30 min with calcium chloride solution. Recovery, based on a universal optical rotation of  $203^\circ$ , is over 95%. While this application of the method needs further verification, several laboratories in an ISO work group report similar findings.

The enzymatic methods are specific for native starch; modification usually hinders the enzyme action. However, the esters acetate, adipate, and

**Table 1** Summary of suitable methods for different starch types

succinate are very labile, and if the substituent is first hydrolyzed under alkaline conditions the starch content can be quantified enzymatically. A summary of the applicability of different methodology to the range of starches likely to be encountered is given in **Table 1**. Evidently, for certain pregelatinized modified starches, no method presently exists for quantification of the starch content.

An enzymatic approach is used to characterize dietary starch, which is observed as falling into different categories according to the speed of digestion in humans: rapidly digestible, slowly digestible, and resistant starch. Total starch is determined by enzyme hydrolysis after dissolution of the starch in potassium hydroxide. The digestible starch is determined by incubation with pancreatic enzymes at  $37^\circ\text{C}$ . Rapidly digested starch is calculated from glucose released after 20 min and slowly digested starch from glucose released after 2 h. Resistant starch is that which is not hydrolyzed within the 2 h.

## Starch Purity

The determination of starch purity, for certain economic reasons, became an important point of discussion in Europe. Whatever the source, starch

**Table 2** Typical analysis of starches from different sources<sup>a</sup>

Source	Moisture <sup>b</sup> (%)	Ash <sup>c</sup> (%)	Fat <sup>d</sup> (%)	Protein <sup>e</sup> (%)	Starch (by difference) (%)
Regular maize	13.13	0.06	0.68	0.37	98.9
Waxy maize	12.65	0.04	0.08	0.22	99.7
Potato	18.85	0.21	0.04	0.09	99.7
Wheat	12.24	0.15	0.56	0.30	99.0
Pea	8.06	0.03	0.09	0.27	99.6
Rice	11.74	0.25	0.71	0.52	98.5

<sup>a</sup>All values are % on dry substance.<sup>b</sup>Moisture determined by drying for 1.5 h at 130°C, atmospheric pressure.<sup>c</sup>Ash determined by pyrolysis at 550°C for 2 h.<sup>d</sup>Fat determined by hydrolysis with acid, and extraction of the residue with petroleum ether.<sup>e</sup>Protein determined by Kjeldahl method.

produced economically from an industrial process will always contain minor constituents, namely protein, fat, and ash. Fiber may also be present but at minute levels. According to the starch type, these will additively represent a maximum of 1.5% of the native starch. As examples, potato starch has little fat or protein and is probably 99.5% pure, while maize starch contains up to 0.6% fat and 0.4% protein, so is less than 99% pure. As all methods for determining starch have optimistically a best tolerance of  $\pm 1\%$ , true starch content is better determined by measuring the minor constituents and subtracting these from 100. Measurement of protein is done by standard methods such as the Kjeldahl or Dumas techniques. It is important, however, that the correct method for fat is used, as a simple solvent extraction is ineffective. To obtain the correct results, the starch must first be hydrolyzed with hot hydrochloric acid, and the resulting residue is collected prior to extraction with petroleum ether. Ash content is usually  $\sim 0.1\text{--}0.2\%$  and is determined by direct combustion in a furnace. Typical composition of six different starches is given in Table 2.

## Qualification of Search

There is no universally accepted definition of starch with regard to minimum chain length or relative molecular mass. A common way of defining starch is by stipulating a certain concentration of ethanol in water solution in which the 'starch' fraction is insoluble. The popular concept of the controlling medium for starch qualification is a 40%, v/v, ethanol solution.

To examine the solubility of starch, a maltodextrin with a low dextrose equivalent of 5 was dispersed in a series of alcohol solutions at different concentrations. After filtration, the solubilized fractions were injected onto size-exclusion columns to determine maximum relative molecular mass  $M_r$ . The results in

Figure 2 show that the recommended concentration of 40% dissolves species of  $M_r$  up to 90 000. The question arises whether the alcohol concentration is too low, as such high  $M_r$  species cannot be classified as oligosaccharides. As expected, the higher alcohol contents show a correspondingly lower limiting solubility. The findings apply only if the original matrix has been fully pregelatinized. With granular starch, only minor amounts of very low  $M_r$  substances are removed. If labeling of foods increases in importance, there may be a need for an international definition of starch.

## Relative Molecular Mass Distribution

Native starches are physically or chemically modified to increase application possibilities, and the relative molecular mass distribution gives an excellent indication of how a starch will perform. The starch might be used as an adhesive, surface size, hydrocolloid, or bulking agent. Size-exclusion chromatography (SEC) is much improved with respect to columns, calibrants, and detectors. First, the starch has to be solubilized without molecular degradation, which eliminates the use of acid and probably alkali. The latter has been proposed but hydrolysis is difficult to avoid. If water is the basic eluent of the chromatography, then a solvent consisting of 90% dimethyl sulfoxide and 10% water is most effective; this ratio is critical. Starch concentration should be as low as possible, and a 0.5% solution gives a concentration adequate for the chromatography. Usually, dissolution is complete after 10 h at 60°C. Cross-bonded starches (e.g., phosphorylated, adipates) cannot be dissolved.

A large number of columns are available for SEC, but this part of the system needs the most careful selection. All packing materials so far evaluated show different degrees of starch adsorption. This can

**Figure 2** Size-exclusion chromatograms of lightly hydrolyzed starch extracted with mixtures of ethanol–water at different ratios. Determination of limiting solubility. Columns, Shodex S803/S801. Solvent, water at 60°C, 1 ml min<sup>-1</sup>. Detection, refractometer. Calibrants, Shodex kit, Pullulan, P802.

be diminished by inclusion of organic solvent, salts, surfactant, or alkali, according to the nature of the packing materials, but doubts may still exist concerning complete elution of the starch. Two packing materials on which only minor adsorption occurs are polystyrene cross-linked with divinylbenzene, sulfonated and in the sodium form, and a copolymer of allyldextran and *N,N*-methylene bis-acrylamide.
